THE PORCELLANASTERIDAE

A MONOGRAPHIC REVISION OF AN ABYSSAL GROUP OF SEA-STARS

By F. JENSENIUS MADSEN
Zoological Museum, Copenhagen

CONTENTS

PREFACE

The Porcellanasteridae s. str. form within the Asteroidea a well circumscribed group the members of which are easily distinguished from all other sea-stars by the presence – in each interbrachial angle – of one or more of the so-called cribriform organs. The group is further distinguished biologically by being exclusively confined to the deep-sea. So far no porcellanasterids have been found in depths less than about 1000 meters, and more than half of the records are from depths exceeding 3000 m.

The present paper reports on the large material of porcellanasterids brought back by the Danish Deep-Sea Expedition on the 'Galathea' in 1950-52, and on a few specimens taken in 1920 by the 'Pickle' of the South African Fishery Investigations. Further the paper summarizes and discusses all which is previously recorded concerning the porcellanasterids.

The study is essentially morphological and taxonomical, but at the same time it forms the main basis of the following paper in this report: On the zoogeography and origin of the abyssal fauna in view of the knowledge of the Porcellanasteridae.

The text-figures illustrating structural details were drawn by means of a camera lucida, but are sometimes slightly diagrammatic; no attention has been paid to the ornamentation of the skeletal elements, and occasionally, in case of defect specimens, the illustrations of the spine-armature have been combined from different plates and ossicles. The author's English was revised by Mrs. A. VOLSØE.

INTRODUCTION

Historical review (expeditions and authors)

The porcellanasterid sea-stars were completely unknown to science until 1873 when they were brought to light during the early part of the first great deep-sea expedition, the famous voyage of the Challenger. Several specimens were then collected in three successive dredgings off the eastern coast of the United States of America on blue mud in depths of 2270 to 2470 m. These specimens all belonged to one and the same species, which was described under the name of *Porcellanaster ceruleus* by WYVILLE THOMSON in 1877 in his preliminary account of the results of the work of the Challenger in the Atlantic. The generic name was suggested by the porcellaneous conspicuous marginal plates which have proved characteristic of all members of the group, and the specific name was suggested by the cobalt-blue colour of the specimens while alive (a colour which probably primarily has been due to the stomach content of blue mud shining through the thin body-wall, all porcellanasterids being "mud-swallowers").

Since the porcellanasterid sea-stars are limited to bathyal and abyssal levels, they have hardly ever been caught except in the deep-water dredgings of collecting expeditions, and the history of their exploration is therefore closely connected with the

history of the great deep-sea expeditions. The principal expeditions having collected porcellanasterids are (with the number of dredgings in which they were taken added in parentheses):

The Challenger 1872-76 (14)
The Talisman 1883 (8)
The Ingolf 1895-96 (8)
The Investigator 1890-1903 (21)
The Princesse Alice 1895-1910 (13)
The Valdivia 1899-1900 (6)
The Albatross 1899-1911 (36)
The Swedish Deep-Sea Expedition 1948 (on the Albatross) (3)

Further also the following expeditions, research-wessels and collectors, have brought back porcellanasterids: the Travailleur 1880-81 (2), the Albatross 1883-84 (42), the Siboga 1899-1900 (3), STANLEY GARDINER about 1900 (1), the Scotia 1904 (2), the Thor 1906 (1), the Pieter Faure about 1910 (2), the Hirondelle II 1912 (1), the Arcturus 1925 (1), the Godthaab 1928 (1), the JOHN MURRAY Expedition (on the Mabahiss) 1935 (1), and the Atlantis 1947 (1).

In this paper is now added the records of the porcellanaterids collected by the Galathea 1950-52 (27 dredgings) and by the Pickle 1920 (1 dredging). Porcellanasterids are further collected in several dredgings during the recent Russian explorations of the Pacific, primarily on the Vitjaz.

In the Atlantic, porcellanasterids were collected in the area south of Greenland and Iceland by the Ingolf (73 specimens from eight dredgings in depths of about 1500 to 3200 m) and the Godthaab (4 specimens from one dredging in 2750 m in the Davis Strait). In the northwestern region off the coast of the U.S.A. a number of specimens were taken by the Challenger in three dredgings in 2270 to 2470 m, and an unknown number by the Albatross[1] in 42 hauls from depths between 1660 and 3520 m. In the eastern region of the North Atlantic, from off France to the Cape Verdes, they were collected by the Thor (2 specimens from a dredging south of Ireland in 1800 m), by the Travailleur (2 specimens from two dredgings in about 2000 m in the Bay of Biscay), by the Talisman (17 specimens from eight dredgings in about 1500 to 4800 m), by the Princesse Alice (30 specimens from thirteen dredgings in depths of about 3500 to 6035 m), by the Hirondelle II (a single specimen from west of Madeira in 5300 m), and by the Atlantis (7 specimens from a single dredging south of the Azores in 3200 m). In the tropical mid-Atlantic the Swedish Deep-Sea Expedition on the Albatross collected 40 specimens at three stations in about 4450 to 5600 m. In the eastern tropical Atlantic the Valdivia collected 33 specimens in 2275 to 4990 m in three dredgings in the Gulf of Guinea, and the Challenger a few specimens in three dredgings in 4300 to 4660 m in the Cape Verde and the Cape regions. In the Cape region 2 specimens were obtained in two dredgings in about 1500 to 1800 m by the Pieter Faure. In the Antarctic, in the Atlantic section, the Scotia collected 4 specimens in two dredgings in about 3850 and 2580 m.

In the Atlantic, the Galathea collected 71 porcellanasterids in six dredgings in the region of the Gulf of Guinea, in depths of 1260 to 5160 m, and the Pickle got some specimens in one haul in the Cape region in 2175 m.

In the Indian Ocean, the Investigator collected more than fifty porcellanasterids in the Arabian Sea and the Bay of Bengal in twenty-one dredgings from between about 1200 and 3650 m. The Murray Expedition collected 40 specimens in a single dredging in about 3850 m in the northern region off East Africa, and the Valdivia 3 specimens in three dredgings in the equatorial region off East Africa and at Sumatra, in depths of about 1650 to 5250 m. STANLEY GARDINER obtained 2 specimens from a depth of about 1000 m or more near Mauritius. The Challenger caught a single specimen in the Antarctic region in 3570 m.

In the Indian Ocean, the Galathea collected 285 specimens in fifteen dredgings distributed along East Africa, from Ceylon to the Bay of Bengal, and south of Java, in depths of 2600 to almost 7000 m.

In the Pacific, porcellanasterids were collected in the region of the Malay Archipelago by the Siboga (13 specimens in three dredgings in depths of about 1150 to 1900 m), and in the Philippine area by the Albatross in 1911 (9 specimens in five dredgings in depths of 905 to 1350 m). The Challenger collected some porcellanasterids in seven dredgings in 1460 to 5030 m, distributed from New Guinea to Japan, in the mid-Pacific, and off Chile. The Albatross collected 209 specimens in thirty-one dredgings in the eastern Pacific from the Bering Sea to off Peru and

1. H. L. CLARK in 1923 notes that he has examined specimens of *Porcellanaster cæruleus* belonging to the Blake collections, but possibly the Albatross collections are meant. According to E. PERRIER in 1884 p. 272, the Blake expeditions at least did not collect any porcellanasterids in the West Indian region.

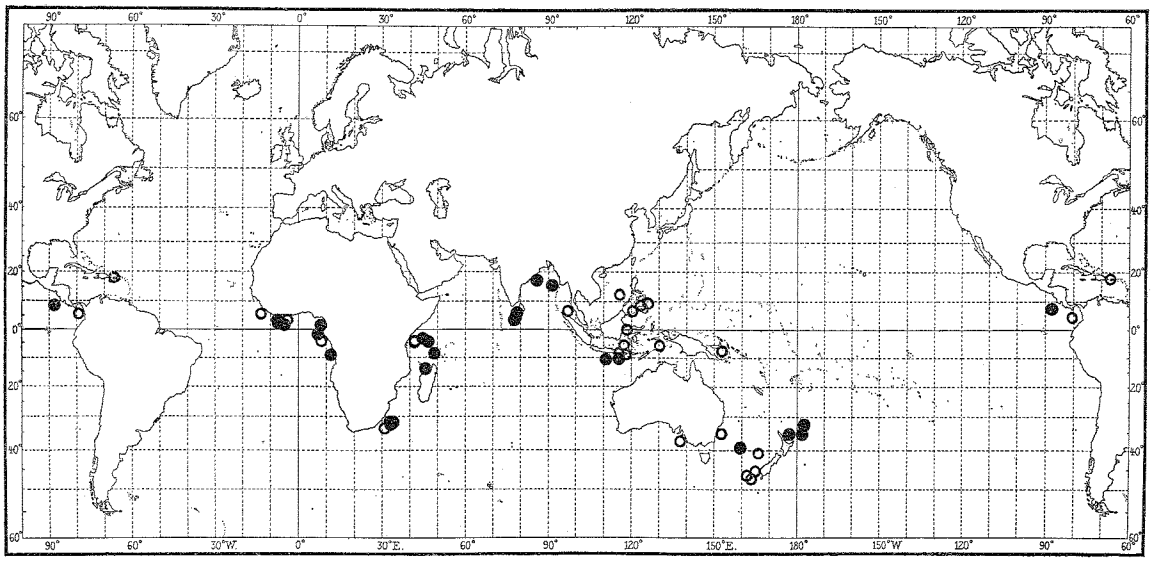

Fig. 1. Map showing the distribution of the 74 successful dredgings undertaken by the Galathea in depths of more than 1000 m. Filled circles indicate the dredgings yielding porcellanasterids.

as far west as the mid-Pacific, in depths of 1400 to 5870 m. The Arcturus got a single specimen in 3170 m in the Galapagos region. The recent Russian explorations have yielded a large material of porcellanasterids from the region of the Kamchatka and the Kuriles.[2]

In the Pacific the Galathea collected 113 specimens in five dredgings in the Australia-New Zealand region and in one dredging in the Panamic region, in depths of 2640 to about 6700 m.

Prior to the Galathea Expedition porcellanasterids were collected in about 167 dredgings, viz. 93 in the Atlantic, 27 in the Indian Ocean, and 47 in the Pacific (10 of the latter dredgings being in the region of the Malay Archipelago). The total number of specimens known at this time was probably about 600-650. The Galathea Expedition obtained porcellanasterids in 27 of the 74 successful dredgings carried through in depths of more than 1000 m, and collected a total number of 469 specimens. (Fig. 1).

The depths of the Galathea dredgings in which porcellanasterids were collected were as follows (with the total number of successful dredgings carried through added in parentheses):

1 between 1000 and 2000 m (10)
6 between 2000 and 3000 m (13)
9 between 3000 and 4000 m (15)
8 between 4000 and 5000 m (21)
1 between 5000 and 6000 m (10)
2 between 6000 and 7000 m[3] (5)

Records of depths are available for 123 of the about 167 dredgings from which porcellanasterids were reported before the Galathea Expedition.

2 were from 905 and 936 m respectively.
30 between 1000 and 2000 m
27 between 2000 and 3000 m
30 between 3000 and 4000 m
23 between 4000 and 5000 m
10 between 5000 and 6000 m
1 in 6035 m

Most of the dredgings of porcellanasterids prior to the Galathea Expedition yielded only one single valid species each. More than one species were obtained in only 28 of the recorded 167 dredgings, viz. two species in 19 dredgings (belonging to the same genus in five cases), three species in 7 dredgings (two species of the same genus in one case, otherwise all three species of different genera), and four species in 2 dredgings (two of the species of the same genus in both cases). In about half, i. e. 13 out of the 27 dredgings of porcellanasterids made by the Galathea Expedition, however, more than one species were secured (which may be considered a proof of the efficiency of the collecting-gear used by the expedition), viz. two species in 5 dredgings

2. Some preliminary information of this material is given e. g. by ZENKEVITCH, BIRSTEIN & BELIAEV in 1955, so that it has been possible to mark some of the finds in the accompanying maps of distribution.

3. The specimens from the two hadal dredgings (6000-7000 m) are mentioned in the Galathea Report vol. 2, in which is dealt with the animals of the extreme depths.

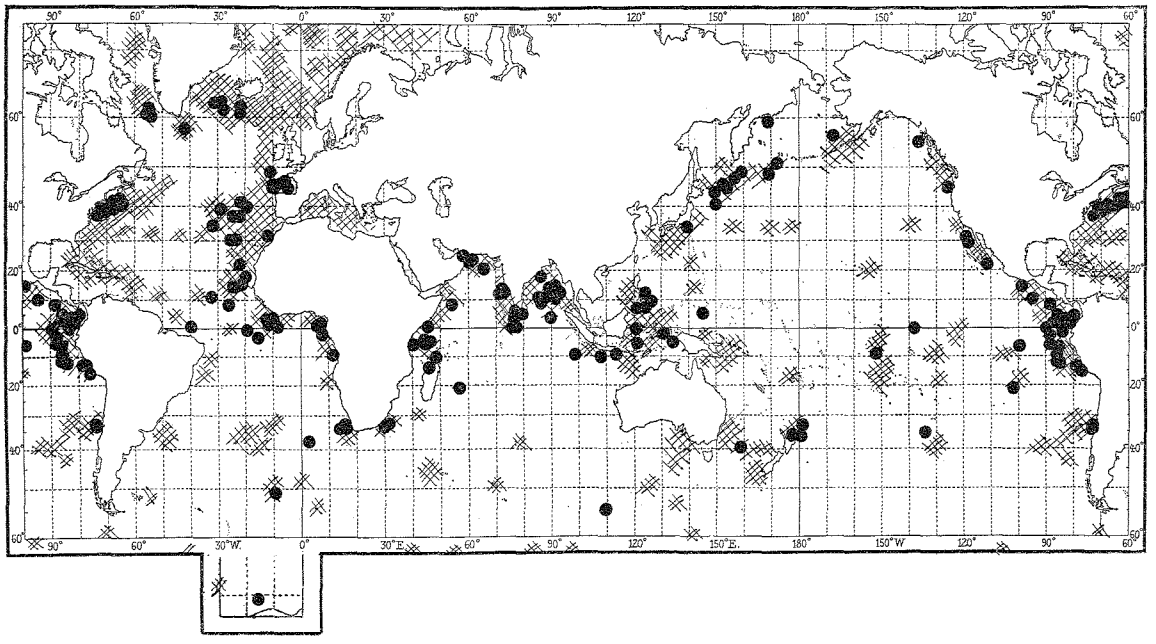

Fig. 2. Distribution of the localities from where porcellanasterids have been obtained. The cross-hatched areas indicate where deep-sea collecting has been undertaken hitherto.

(belonging to the same genus in one case), three species in 4 dredgings (two of the species of the same genus in one case), four species in 3 dredgings (two species of the same genus in one case), and five species in 1 dredging (viz. st. 282 in the Indian Ocean, at which 59 specimens of the genera *Hyphalaster, Abyssaster, Thoracaster, Styracaster,* and *Porcellanaster,* were brought up).

The present author has himself reported on the 40 specimens of porcellanasterids collected by the Swedish Deep-Sea Expedition, and has further had the opportunity to re-examine the specimens collected by the Ingolf, the Thor, the Godthaab, and the Valdivia. Through the courtesy of dr. DEICHMANN of the Museum of Comparative Zoology at Harvard, the author was enabled also to examine specimens of three different forms of porcellanasterids from the Albatross expeditions in the eastern Pacific. Thus the author has had a total of 628 specimens passing through his hands and has examined representatives of all porcellanasterid genera recognized, except the two bathyal genera: *Lysaster* and *Benthogenia.*

The principal authors who have dealt with the Porcellanasteridae, after WYVILLE THOMSON had described the first one, the type of the group, are the following:

1) SLADEN (1883, 1889) who took over the working up of the Challenger material of sea-stars when WYVILLE THOMSON due to illness had to give it up, 2) E. PERRIER (1884, 1885, 1894) who described the materials collected by the Travailleur and the Talisman, 3) WOOD-MASON & ALCOCK (1891, 1893) who dealt with the collections of the Investigator, 4) KOEHLER (1907, 1908, 1909, 1921) who treated the specimens collected by the Princesse Alice, the Hirondelle II, and the Scotia, and also revised those of the Investigator, 5) LUDWIG (1905, 1907) who reported in detail on the earlier collections of the Albatross in the eastern tropical Pacific, and preliminarily considered some of the later Albatross collections, and also the Valdivia material, 6) FISHER (1905, 1907, 1911, 1913, 1919, 1928) who treated some other Albatross collections, especially from the northern East Pacific and the Philippine region, and also dealt with the Arcturus find, and 7) LIEBERKIND (1932, 1935) who treated the Ingolf material and also worked up the final report on the Valdivia collection. Further reports on porcellanasterids including descriptions of new forms were published by 8) BELL (1909), (who was not aware, however, that he dealt with a porcellanasterid), 9) by DÖDERLEIN (1921), who reported on the Siboga material, and 10) by MACAN (1938) who reported on the collection of the John Murray expedition. Finally, also the following authors have reported on porcellanasterids, but without naming new forms, viz. VERRILL (1885, 1895) on the Albatross collections in the N. W. Atlantic, H. L. CLARK (1913, 1920, 1923) on materials from the Albatross ex-

plorations in the eastern Pacific, A. H. CLARK (1948) on the specimens from the Atlantis Expedition, DJAKONOV (1950) on a specimen from the Russian explorations S. E. of Kamchatka, A. M. CLARK (1952) on the specimens originally described by BELL, and the present author (1951, 1956) on the collection of the Swedish Deep-Sea Expedition, and on the material of the Galathea Expedition from depths exceeding 6000 m. The porcellanasterids collected in the Pacific by the Vitjaz are under consideration by BELYAEV.

General remarks on taxonomy and morphology

The group Porcellanasteridae which was erected by SLADEN to embrace *Porcellanaster* and its relatives was first, in the preliminary report in 1883, registered as a sub-family of the Astropectinidae. But in 1889, in the final edition in the Challenger report in which SLADEN gives a new classification of the Asteroidea, the Porcellanasteridae are listed as the second family of the order of Phanerozonia, comprising two sub-families, the Porcellanasterinae (= Porcellanasteridae sensu Sladen 1883) and the Ctenodiscinae. SLADEN gives as reason for now associating the porcellanasterids s. str. with the genus *Ctenodiscus* that the structure of this sea-star in many ways indicates a community of descent and shows a much closer relation to the porcellanasterids s. str. than to the astropectinids. WYVILLE THOMSON in 1877 in his description of the first porcellanasterid had mentioned too that it seemed to be related to *Ctenodiscus*. However, SLADEN – besides noting the affinity between *Ctenodiscus* and the group of porcellanasterids s. str. – also points out that they at the same time differ so considerably that the separation into two distinct subfamilies appears justified. FISHER in 1911 noted that the Porcellanasteridae might be considered of the rank of a suborder, which he named the Cribellosa (coordinate with the Paxillosa, the Valvata, and the Notomyota, within the order of Phanerozonia), and subsequently, in 1916, he transferred the Ctenodiscinae to the Goniopectinidae (of the order of Paxillosa), and the concept of the Porcellanasteridae then became the one adopted in the present paper.

The generic names applied to the Porcellanasteridae s. str. are in their chronological order the following:

Porcellanaster Wyville Thomson, 1877
Caulaster Perrier, 1882
Styracaster Sladen, 1883
Hyphalaster Sladen, 1883
Thoracaster Sladen, 1883
Machairaster Perrier, 1884
Pseudaster Perrier, 1885
Eremicaster Fisher, 1905
Albatrossia Ludwig, 1905
Chunaster Ludwig, 1907
Albatrossaster Ludwig, 1907
Sidonaster Koehler, 1909
Lysaster Bell, 1909
Benthogenia Fisher, 1911

An additional genus, *Abyssaster* gen. nov., is erected in this paper for some of the species hitherto referred to *Hyphalaster*, and the description by BELYAEV of another genus, *Vitjazaster*, for a new species from the West Pacific, *V. djakonovi*, is in press.

The genera *Ctenodiscus* Müller & Troschel, 1842, and *Pectinidiscus* Ludwig, 1900, which may be found listed as porcellanasterids, belong to the group Ctenodiscinae now referred to the family Goniopectinidae of the suborder Paxillosa.

A number of the above listed generic names have fallen into synonymy, thus *Caulaster* was based on a juvenile *Porcellanaster*, *Machairaster* is a simple synonym of *Styracaster*, *Pseudaster* was based on a juvenile *Thoracaster*. *Albatrossia* was probably based on a juvenile *Porcellanaster*, *Albatrossaster* was merely a new name to replace *Albatrossia*, and *Chunaster*, as will be demonstrated in the following, is identical with *Styracaster*.

The four genera which SLADEN recognized within the Porcellanasteridae: *Porcellanaster*, *Styracaster*, *Hyphalaster*, and *Thoracaster* (with 6, 2, 4 and 1 species respectively) all stand, only his *Porcellanaster* has been subdivided into *Porcellanaster* s. str. and *Eremicaster*, and his *Hyphalaster* will in the following be separated into *Hyphalaster* s. str. and *Abyssaster*. Also nearly all the species recognized by SLADEN are valid. In fact, already the material collected by the Challenger Expedition was so representative of the porcellanasterid fauna of the deep-sea that up to this time it has not been possible to add anything of much importance to the account which SLADEN gave in his outstanding report. The Challenger material thus included representatives of all the abyssal genera of porcellanasterids described to this day[4];

4. The Vitjaz collections, however, include a new abyssal porcellanasterid genus: *Vitjazaster* Belyaev, in press.

the remaining recognized genera which were not represented in the Challenger collection, viz. *Sidonaster, Lysaster,* and *Benthogenia,* being – so far as is known – confined to the deeper bathyal zone.

The three porcellanasterid genera established by PERRIER all have proved to be synonyms of formerly described ones, and probably also all his nine species are only synonyms. The single genus described by KOEHLER is valid, but less than half of the ten species, he named, are so. One of the two species described by WOOD-MASON & ALCOCK is valid, while the other is uncertain. Both two genera erected by LUDWIG fall into synonymy, and only about one-third of the thirteen species, he described, can be maintained. The two genera erected by FISHER are both valid, and so are also two of the three species he described. The single species (and genus) described by BELL is distinct. But neither the single species described by DÖDERLEIN and nor the two forms described by LIEBERKIND can be maintained, and also the single species described by MACAN is uncertain.

Diagnosis:

The Porcellanasteridae (= suborder Cribellosa) are five-armed phanerozoniate sea-stars with very conspicuous, large thin porcellaneous marginal plates, and are primarily distinguished by the presence – in each arm angle – of one or more of the so-called cribriform organs.

The cribriform organ is a term created by SLADEN in 1883 for a peculiar structure present in each arm-angle of all porcellanasterids (and in this special form not found in any other group of sea-stars). WYVILLE THOMSON when in 1877 he described the first porcellanasterid, *Porcellanaster cæruleus,* noted the close covering of spinelets on the marginal plates in the arm-angles as a conspicuous character. He spoke of it as an ornament, and he also compared it to a little brush. It was SLADEN, however, who first gave a detailed description of the structure.

Every cribriform organ consists of a number, e.g. 20-30, of close-set skin folds or rows of minute papillae situated on a pair of adjacent marginals, to both sides of the vertical sutures between them, extending (in the case of fully developed organs) from the dorsal edge of the superomarginal plates to, or almost to the ventral edge of the inferomarginal ones, inwardly supported by microscopic calcareous papillae (compressed spinelets or plates), and outwardly clothed with a ciliate epithelium. Laterally each cribriform organ has a fringe of usually at least slightly larger and more robust and often flattened calcareous papillae (spines, or possibly fairly broad plates). This outer series, possibly united by a distinct web, may extend from the dorsal edge of the superomarginal plate to the ventral edge of the inferomarginal one, on either side of the organ, or – as is generally the case – it bends round close to the ventral edge and continues along the lower end of the cribriform organ up on its other side to the dorsal edge of the other superomarginal plate. The cribriform organs are thus rather indistinctly marked off from the spine- or paxil-bearing disk area, whereas they are usually well demarcated ventrally.

The cribriform organs are developed on more or less marked depressions on the marginal plates. The fringe of covering papillae can be bent away from the ciliated series of papillae or lamellae, so that these are fully exposed. But the ciliated epithelium can also be well protected by the series of papillae or lamellae being closed down upon each other in direction towards the vertical suture medially, and the covering papillae closing down upon them laterally. (Very aptly, the lamellae have been compared to the leaves of a book).

There is only a single cribriform organ in each arm-angle in *Porcellanaster* and *Sidonaster,* whereas there are three cribriform organs in each arm-angle in *Eremicaster* (though in juvenile specimens initially only a single one, and in very large (old) specimens occasionally as many as five organs). Three cribriform organs in each arm-angle similarly is the normal number in some species of *Abyssaster* and *Styracaster.* But other species of these two genera may have up to eleven cribriform organs in each interradius, and then the number often increases with age. The two only known specimens of *Lysaster* had in each arm-angle seven cribriform organs, which is one at every interbrachial vertical suture. The only known full-grown specimen of *Benthogenia* had cribriform organs developed around every single one of all the vertical marginal sutures of arms as well as of disk.

New cribriform organs are normally formed bilaterally to either side of the initial series of organs, and always around successive vertical sutures, no case being known of a suture having been skipped. In all the genera just mentioned there is a mid-interradial vertical suture, and therefore there is normally an odd number of cribriform organs in each interradius. In the genus *Thoracaster* there is a marginal plate mid-interradially, and thus an even

number of cribriform organs in each interradius is the rule here, – in grown-up specimens often 12-16; but exceptionally up to e. g. 24, in which case cribriform organs occur also proximally in the arms.

The outermost and youngest cribriform organs are usually composed of a smaller number of rows of papillae than the innermost ones, and are often quite rudimentary, e. g. yet consisting of only a single row of papillae to the proximal side of the vertical sutures. The rudimentary cribriform organs are also sometimes formed from the ventral margin, in which case the rows of papillae decrease in number in vertical direction and may not yet reach the superomarginal plates. In other cases the rows of papillae are formed simultaneously from the ventral and the dorsal margins; occasionally they are formed first from the dorsal margin, and exceptionally their median part, at the horizontal suture, is the first to become developed. The width of the cribriform organs increases with age of the sea-star, so that in large (old) specimens of several forms the innermost cribriform organs often show a tendency to merge together, especially medially around the horizontal suture, but sometimes also dorsally and ventrally, and exceptionally only in these latter places.

SLADEN (1883 p. 217 and 1889 p. 128) noted concerning the structure of the cribriform organ that the component parts in *Porcellanaster* (i. e. *Porcellanaster* s. str. and *Eremicaster)* were strictly lamellar in form (the calcareous compressed papillae supporting the ciliated folds placed end to end together and thus forming an apparently continuous lamella), while they were papilliform (composed of distinct, free and independent papillae) in *Hyphalaster* (i. e. *Hyphalaster* s. str. and *Abyssaster), Styracaster* and *Thoracaster*. – This holds true in broad outline, but it may sometimes be difficult to decide whether a certain cribriform organ is of a lamelliform or of a papilliform structure. In some specimens of *Styracaster* for instance (cf. p. 115) the cribriform organ must be described as lamelliform; and the supplementary cribriform organs which are sometimes formed in large specimens of *Eremicaster* (cf. p. 154) are papilliform as distinct from the lamelliform structure of the three organs which normally occur in the genus. In *Sidonaster* the cribriform organ is of a papilliform structure with very long and slender papillae, arranged very distinctly in quincunx. (The papilliform cribriform organs may also be described as spiniform).

SLADEN noted (1883 p. 217, 1889 p. 128) that "The number of cribriform organs present in each angle appears to be always constant in a species; and species exist which possess 1, 3, 5, 7, 9 or even 14 of the organs respectively". SLADEN himself, however, records a variation of from 7 to 9 cribriform organs in his *Styracaster horridus,* so that a concept of a specifically fixed number of cribriform organs should not be taken too literally. The larger materials of porcellanasterids which have later become available, also show that the number of cribriform organs not only increases with age, but is also subject to individual variation in equal-sized specimens, and may even vary in the different interradii of the same specimen. In general the number of cribriform organs if exceeding three in each interradius can be considered as inconstant and be expected to vary individually.

In the species in which there is a larger number of cribriform organs, three, five, or maybe even seven such organs become developed simultaneously in each interradius in the juvenile specimens, often with the series in the interradius with the madreporite formed slightly earlier than those in the other interradii.

It appears from this account of the cribriform organs that their number is only of little – if any – importance in the taxonomical description of a species, and that also a character as their width is of no specific value.

The original porcellanasterids probably had cribriform organs developed at every marginal suture (corresponding to that the related Goniopectinidae and Astropectinidae have fascioles between all the marginals). In the recent porcellanasterids a great number of cribriform organs therefore may be considered the more primitive feature, while the possession of only a single cribriform organ in each arm-angle may perhaps be regarded as a paedomorphic feature established during evolution. (The recent porcellanasterid genera with many cribriform organs also include those with the least specialized adambulacral and oral armature).

The cribriform organs appear in the living porcellanasterids as yellowish or orange vertical bands on the otherwise usually pale greyish or pale yellowish pink animal. In the preserved specimens they may be marked off by being covered with mud caught in their slime secretion.

SLADEN notes (1883 p. 216) about the cribriform organ that "it is not improbable that it functioned as a percolator; and in such a case it might perhaps be looked upon as the homologue of the minute

spines which border the vertical furrows that run between the consecutive marginal plates in *Astropecten* and other forms."

GISLÉN (1924) studied the feeding behaviour of *Ctenodiscus* – a very sluggish animal, with a simple type of cribriform organs, and like the deep-sea porcellanasterids a mud-swallower. When laid down on a natural mud bottom *Ctenodiscus* ploughed itself half way down into the mud. And when picked up again, it could be seen that the ciliary grooves (or the fasciolar channels) of the ventral side (which extend from the marginal sutures to the ambulacral grooves) were filled with mud glued into strings of mucus. Mud stuck together by mucus was further present around the podia, and the mouth was covered by a veil of mucus leading into the stomach. GISLÉN notes that quite probably the respiration is provided for by the ciliary currents created by the cribriform organs (in accordance with SLADEN's view that the cribriform organs served to purify the respiration water), but he stresses that it is a fact that small particles are carried along the grooves of the cribriform organs to the ambulacral groove, to be transported thence to the mouth.

LIEBERKIND (1935 p. 34) states about the simple cribriform organs in *Ctenodiscus* that "... the lamellæ are seen to be covered with a thick columnar ciliated epithelium. In numerous places amoebocytes are found, which are about to penetrate the epithelium; this might indicate that it also plays a part as a kind of excretory organ."

CUENOT (1948 p. 211) says about the cribriform organs in the Porcellanasteridae and the homologous organs in the Ctenodiscinae that "Ils doivent probablement determiner des courants nettoyeurs, car il n'y a que peu ou point de papules chez les Porcellanastérides; il est possible aussi qu'ils remplacent les papules au point de vue de la phagocytose éliminatrice, car on a remarqué qu'ils renferment beaucoup de cellules migrantes qui traversent l'épithélium."

HYMAN (1957 p. 382) follows CUENOT in stating that the cribriform organs (of porcellanasterids and *Ctenodiscus)* presumably take the place of the papulae which she considers mostly lacking in the porcellanasterids, and follows GISLÉN in stating that the cribriform organs are "assumed in the want of other evidence to have a respiratory function, as water currents pass between their lamellae" and that "possibly, however, they also serve as detritus catchers by the mucus ciliary method as is known to be the case in *Ctenodiscus*".

Now, the porcellanasterids must live as burrowers, and in the opinion of the present author the function of the complicate cribriform organs, therefore, must be to create and maintain a circulation of water around the animal in its burrow, a channel presumably being kept open to the surface by means of the apical cone or appendage (a structure to be considered later). And, no doubt the ciliary actions, besides supplying fresh water for respiration, also serve to draw down from above surface-matter to be caught in a secretion of mucus and led to the mouth (see also p. 50).

The furrow skeleton of the porcellanasterids is – like the marginal plates and the cribriform organs – very characteristic of the group as a whole, and offers at the same time one of the best specific characteristics.

The terminology used in the present paper in the descriptions of the different skeletal elements is the same, in the main, as commonly used in modern literature on sea-stars. Only the adambulacral and oral skeletal elements are preferred termed ossicles instead of plates, these skeletal parts not at all being plate-shaped. On the other hand, all movable calcareous parts found on these ossicles and on the marginal plates etc., may be termed spines, even if they are not spiniform but e. g. granuliform or spatulate. Also the term papilla, however, may be used for such parts, as for instance in the cribriform organ. The terms 'actinal' and 'abactinal' are in the literature in general use for the oral and aboral sides, or ventral and dorsal sides, which latter designations are employed in the present paper. The term 'ray' is often used for the radial prolongations which more commonly, and also here, are called arms. Most other terms used presumably are self-explanatory.

The adambulacral ossicles are fairly large. The proximal ones are in contour rather subrhomboid in most genera, whereas the more distal ones are rather subcrescentic, with a narrower distal part and a distinct concavity aborally on their furrow side to give room for the tube-foot; and all the adambulacralia are shaped in this way in *Eremicaster, Porcellanaster,* and *Sidonaster.*

On their furrow edge the adambulacral ossicles bear a series of from two to about six so-called adambulacral spines or furrow spines. All furrow spines and oral spines are united by a more or less distinct basal web. In the genera with rather subrhomboid adambulacralia *(Hyphalaster, Benthogenia, Lysaster, Thoracaster,* and *Abyssaster)* the furrow spines are subequal in shape and uniformly spaced, so that they together form a continuous straight or wavy series along either side of the furrow. In *Styracaster* the adoral protruding margin of the adambulacralia bears two or a few close-set spines, whereas the aboral part is naked or with a

single or a few isolated larger spine(s). In *Porcellanaster, Eremicaster,* and *Sidonaster,* the furrow spines are always exclusively confined to the protruding adoral part of the adambulacral ossicle, and the distal part of the furrow margin naked. In *Porcellanaster* s. str. the furrow spines may form pedicellariae; and in *Eremicaster* the distal one may be modified as a so-called segmental papilla (see below), so that here there is only a single spine to protect the tube-foot.

The furrow spines are raised at right angles to the ventral surface when the furrow (the ambulacral groove) is opened and the tube-feet (or podia) protruded, but are bent down and crisscrossed over the furrow when the tube-feet are retracted. The ambulacral groove may also be entirely shut in by the adambulacral ossicles of either side arching over it and almost meeting, possibly being a little displaced in relation to each other so that the protruding adoral part of one ossicle fits into the aboral concavity of its opposite companion. The ambulacral groove when fully expanded may occupy the whole of the ventral side of the arms, and may then, in *Styracaster* and *Porcellanaster* e. g., show a petaloid appearance.

The adambulacral ossicles on their ventral surface may bear a subambulacral armature of spinelets or granules in a varying number, but they can also all be naked without exception as e. g. in the genera *Porcellanaster, Eremicaster,* and *Sidonaster.*

The adambulacral ossicles increase in number with growth of the sea-star by new ones being formed in front of and below the terminal ossicle, and often the armature of the distal adambulacral ossicles is not yet fully developed.

The oral ossicles of the porcellanasterids are large and as a rule very conspicuous. Their shape is fairly uniform throughout the group and has been described as ax-shaped or coulter-like (the exposed surface). The two ossicles, oralia, which form the jaw usually meet proximally and medially, between which two places of contact there is an often fairly broad suture. The oral ossicles in each combined pair, however, may have their whole proximal half in an almost continuous contact, or they may join each other only at their most proximal end. The sutural part of the oral ossicle is raised more or less abruptly above the main ventral surface, and each jaw thus shows a prominent broad median keel or rounded protuberance. Each of the oral ossicles bears on its margin a series of from a few to about fifteen spines (so-called oral spines). The proximal one of these, the mouth-spine, is usually by far the largest. The other, lateral ones are generally subequal, and similar to the proximal adambulacral spines. In some genera the lateral oral spines may be modified as so-called segmental papillae (see below). In *Porcellanaster, Eremicaster,* and *Sidonaster,* the two oral ossicles forming a jaw bear only a single mouth-spine in common on their proximal junction (but two mouth-spines, one to each ossicle, may occur on some jaws, perhaps as an atavism). When the mouth is closed the marginal oral spines interlock and protect the peristome.

The oral ossicles may be provided with a varying number of spines or spinelets on their ventral surface (the suboral armature), sometimes – in large specimens of *Thoracaster* e. g. – forming a close covering. However, the surface of the oralia in *Porcellanaster, Eremicaster,* and *Sidonaster,* is always naked.

The primary oral ossicle (fig. 3*k-n*) is generally well exposed between the distally diverging oralia, and this is a special feature of the Porcellanasteridae. This skeletal element (the primary oral ossicle as it is termed by FISHER 1911 p. 27 e. g., or – as called by authors – impaired interbrachial ossicle, first interbrachial ossicle, first intermediary ossicle, or odontophore) was distinctly and correctly described by SLADEN, but in later papers it nevertheless may be seen described as a ventrolateral plate. It is best observable in dried specimens, whereas it may be obscured by the integument in specimens in alcohol. In *Hyphalaster* and *Thoracaster,* it may sometimes bear a few spinelets, but generally its surface is naked. It is of a fairly uniform appearance throughout the group, triangular with two basal lateral wings on which the oral ossicles are articulated. (Concerning the oral skeleton see further p. 49).

Segmental organs: SLADEN (1883 p. 226, 1889 p. 128) recorded from his *Porcellanaster crassus* and *P. gracilis* (now both referred to *Eremicaster)* a special modification of the surface of some of the oral and adambulacral ossicles and of their spines, which he termed the segmental pits and papillae and described as follows: "These are peculiar structures situated on the adambulacral plates and the mouth-plates. They consist of a pit which occupies the median area of the ambulacral plate, and is guarded by a small scale-like papilla articulated on the surface of the plate at the side of the pit nearest the furrow. The papilla is capable of being shut down, closing the cavity or pit like a lid; but as to the function of these organs I am quite ignorant. The

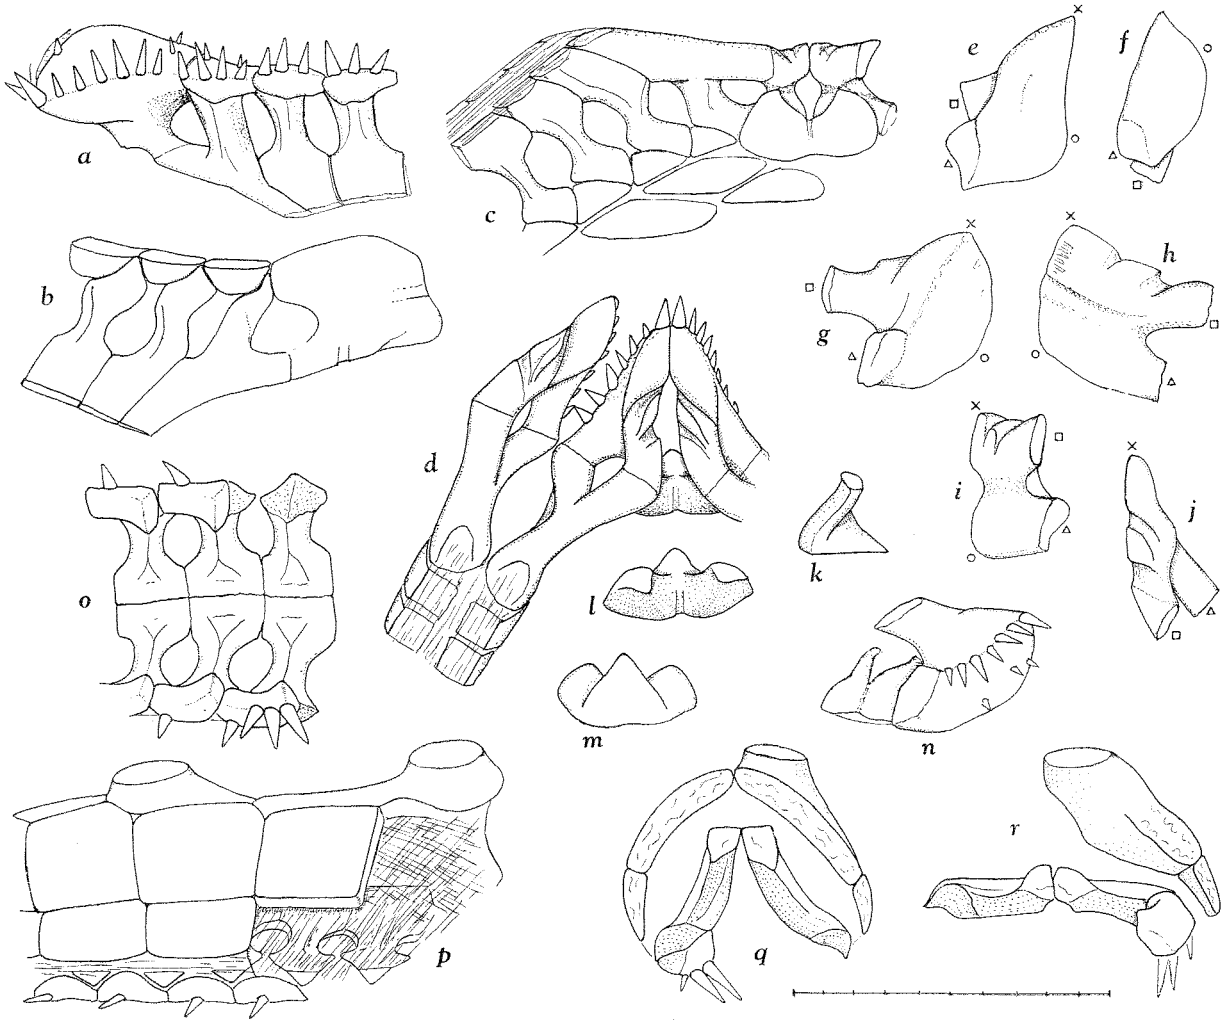

Fig. 3. Skeletal elements of medium-sized specimens of *Styracaster chuni* (R ab. 60 mm) from Galathea st. 99: a) Oral and circumoral ossicles with proximal ambulacralia and adambulacralia, as seen from the furrow side; b) same from the interradial side. c) Part of oral frame as seen from the interradial side; d) same in dorsal view. e-j) An oral ossicle in different views; e, ventral side as usually represented in the figures; f, slightly more turned; g, furrow side; h, interradial side; i, distal end; j, dorsal side; × marks the proximal end where the proximal marginal spine is placed; ○ marks the distal interradial (or the medial) part of the exposed surface, adjacent to the proximal end of the primary oral ossicle; △ marks the distal radial end, in e, f, g with the facet adjacent to the first adambulacral ossicle exposed, in i, j with the facet joining the ventral fork of the circumoral ossicle exposed; □ marks the distal dorsal end which joins the dorsal fork of the circumoral ossicle. k-l-m) A primary oral ossicle, in lateral view, in dorsal view and in ventral view respectively. n) An oral ossicle with the primary oral ossicle in position, as seen from the furrow side. o) Three pairs of ambulacralia with adjoining adambulacralia in ventral view (partly the same as shown in fig. p), furrow spines are shown on only one ossicle, while the subambulacral spine appears on all of them. p) Basal part of an arm, with the superomarginal plate no. 5 and the inferomarginals nos. 5-6 removed on the left side so that the entire ambulacral ossicles are exposed. q) An arm in cross-section, with the furrow closed, seen in aboral view, showing a pair of opposite superomarginals, one of them having borne an arm spine, the adjoining inferomarginalia, a pair of ambulacralia, and an adambulacral ossicle proximal to one of them. r) Basal part of an arm in cross-section, with the furrow opened, seen in adoral view, showing a superomarginal plate of the first joining pair, the accompanying inferomarginal plate, a pair of ambulacralia, and an adambulacral ossicle.

cavities are filled with a dark-coloured substance which may be either foreign or excreted matter."

LUDWIG (1905 p. 93), when considering the said structure, wrote that "Der Boden dieses Grübchens trägt einen feinen, weichen länglichen Wulst von unaufgeklärter Bedeutung, der offenbar von den gewölbten Plättchen beschütz wird."

The possession of these so-called segmental organs was considered a character of generic value by LUDWIG. It has been found, however, that they are of a very unstable occurrence. Within one and the same population they may be developed on adambulacral ossicles for a very varying length of the arms and may also in some specimens be totally

absent (replaced by spiniform spines). In the literature the said organs are recorded only from specimens of the genus *Eremicaster*; but also the adambulacral armature in *Abyssaster tara (Hyphalaster t.)* and in *Styracaster horridus* (syn. *Chunaster scapanephorus)* may be described as forming segmental organs.

FISHER (1911 p. 25) in his description of the adambulacral plates of his *Eremicaster tenebrarius (= E. gracilis)* states that there is "one segmental papilla which is transformed into a spinelet distally on ray"; but, naturally, the reverse is the case, viz. that it is the aboral and normally spiniform furrow spine which on the more proximal adambulacral ossicles is modified as the spatulate spine called a segmental papilla.

The segmental papillae in *Eremicaster* obviously are homologous to the aboral spiniform furrow spines, and actually the so-called segmental organs may have no special function at all, the segmental papilla merely being a structural variant of the spine (cf. p. 50). In those specimens of *Porcellanaster* s. str. in which the furrow spines form pedicellariae, these too may be laid back into a pit on the surface of the adambulacral ossicles, corresponding to the segmental pit in *Eremicaster* into which the segmental papilla fits.

The ambulacral ossicles (fig. 3 *o, q, r)* are rather dumb-bell-shaped. Their radial lateral end is cut squarely so that the opposite joining ones become in direct continuation of each other when the furrow is fully opened; all the ambulacralia then together forming a flat floor in the bottom of the furrow. Their median narrow part leaves room for the single series of pointed podia to each side in the furrow. Their interradial lateral end is cut obliquely adorally and aborally and join up to the aboral and adoral ends of two successive adambulacralia respectively. The lateral ends of the ambulacral ossicles may then appear as small triangular "plates" outwards of, and alternating with the adambulacralia. SLADEN does not mention anywhere in his text that the ambulacralia in the porcellanasterids thus may be visible between the adambulacralia, but the feature appears from his pl. 20A figs. 9 and 10, showing the ambulacral and the adambulacral ossicles of a specimen of *Porcellanaster cæruleus* in different views, and fig. 2 showing a specimen of the same species in ventral view; further also from pl. 24 fig. 2 showing a *Styracaster armatus* in ventral view.

Since SLADEN did not explicitly point out the visible ends of the ambulacral ossicles, some later authors have fallen into the trap of considering them a series of ventrolateral plates (e. g. PERRIER in 1894 with regard to *Styracaster,* and DÖDERLIN in 1921 with regard to *Porcellanaster* and *Sidonaster)* or as supplementary adambulacral plates. The misinterpreted ends of the ambulacral ossicles – when observed in some specimens – have been considered of specific taxonomic importance too, as e. g. when LIEBERKIND in 1935 on the basis of this character supported PERRIER's species *Porcellanaster granulosus.* The only reference and correct description of the visible ends of the ambulacral ossicles (common in more or less marked degree to all porcellanasterids) was given by FISHER (1911 pp. 26 and 30) with regard to his *Eremicaster tenebrarius* and *E. pacificus.*

Superambulacral ossicles do not seem to be present in any of the genera of the Porcellanasteridae s. str. (i. e. with *Ctenodiscus* and allies removed).

The marginal plates of the porcellanasterids are large and thin, subquadrate, subrectangular or subrhomboid. Usually they form an even contour to the body, and the sutures are often indistinct until the specimens are dried. The superomarginal plates and the inferomarginal ones are as a rule of about equal size in the arm angles, whereas in the arms the inferomarginals become progressively lower than their superomarginal companions, the plates of both series diminishing gradually as they proceed along the arms. In well expanded specimens the marginal skeleton forms a gently rounded or perpendicular wall to the body, the dorsal and ventral surfaces of which slope upwards and downwards from it respectively. In specimens with empty stomach the height of the marginal skeleton may represent the height of the body, and the marginal plates may even arch somewhat over the dorsal as well as the ventral side.

The superomarginal plates of either side of the arm, from about the fifth or sixth opposite pair, meet in several genera in the median dorsal interradial line, and are then more or less curved (fig. 3*q)* and the first ones which encase the arm higher, to a varying degree, than those bordering the disk. The joining of the opposite superomarginals, which gives the arms the characteristic narrow shape, is a peculiarity of *Hyphalaster, Lysaster, Benthogenia, Thoracaster,* and *Styracaster,* and is a feature met with in only few other sea-stars.

The superomarginals may be armed with one or a few erect spines or spinelets, placed on or near their dorsal edge. The possession of a superomar-

ginal spine-armature is to some degree a character of age, and is also often individually variable in full-grown specimens of the same population. The character is therefore not always of much taxonomic value. In *Styracaster* the arm spines are erect, immovably fixed, and arranged in a single row along the mid-dorsal arm-line; the spine-bearing plates being larger than the opposite ones and reaching over the midline. The number of arm-spines usually vary somewhat in different specimens from the same population, but there is in this genus (i. e. in all specimens known) at least one dorsal spine on each arm, belonging almost without exception to the first pair of joining superomarginals. The marginal plates are otherwise except for the dorsal spines and the cribriform organs in general naked, only in *Thoracaster* there may be a more or less developed armature of spinelets on the superomarginal as well as on the inferomarginal plates.

The inferomarginal plates are in the arm angle situated exactly below their superomarginal companions, and the same may be the case in the arms, but here the plates of either series may also alternate more or less regularly, and the arrangement may vary in the different arms of the same specimen, even in different parts of the same arm. Similarly the superomarginal plates of either side of the arms may be placed exactly opposite each other or may subalternate, also their arrangement being individually variable. The arrangement of the marginal plates thus cannot be used taxonomically.

The first inferomarginal plates seem to be formed a little later than the superomarginal ones, and in juvenile specimens therefore also the interbrachial inferomarginals may be lower than the superomarginals. Young specimens may also show a larger number of superomarginals than of inferomarginals, whereas the reverse is the general rule in the grown-up specimens, which often have at least one or two superomarginals more than inferomarginals, in consequence of that the terminal ossicle – in front of which the new marginal plates are formed – lies more or less dorsal to the arm end.

While the normal growth of the arms takes place by the interpolation of skeletal elements in front of and below the terminal ossicle, matters may be somewhat different in the case of regeneration of lost arms. It may also in such cases happen that marginal plates form a termination of the broken arm immitating a terminal ossicle.

The shape of the arms in section is subcylindroid in most of the forms in which the arms are encased by the superomarginals, but in *Styracaster* the arms are compressed, and when here a continuous series of arm spines is developed, the arms assume a distinctly keeled shape. The arms when encased by the superomarginals, are usually sharply marked off from the disk, more or less rigid and incapable of being curved to any marked degree; only if long they may be able to curve somewhat horizontally (cf. pl. X 1-2). The arms in the other forms, in which a strip of dorsal integument extend to the terminal ossicle, are less distincly marked off from the disk, flattened or subcylindroid respectively, depending on the state of contraction or inflation of the specimen, and capable of being well curved back. Specimens of this type with empty stomachs and very much contracted, may have the dorsal integument sunk below the upper edges of the superomarginal plates and these arching over the arms so as to actually touch their opposites.

The normal feature of a marginal suture in the interradial mid-line in all genera known, except *Thoracaster* (and *Vitjazaster* Belyaev in press), apparently is subject to individual variation in rare cases, cf. figs. 6*a* and 19*a*.

The terminal ossicle is usually large, larger than in most other sea-stars, with the exception of e. g. some goniasterids. It is one of the earliest formed skeletal elements, and in the juvenile specimens it is thus relatively larger than in the adults. It changes somewhat in appearance with growth in the juveniles before assuming the final form; e. g. it has initially a concave proximal margin, also in the species in which it in the full-grown specimens is convex proximally, and it may at first be distal to the arm end, even if dorsal in position in the adults. The shape of the fully formed terminal ossicle can also vary somewhat within the species, and e. g. the number of spines borne on it may be very variable. In the different genera, however, the main appearance of the terminal ossicle is sometimes so divergent that it may be used taxonomically, though with caution, and in a few cases it may even be used in characterizing a species.

Sea-stars, when mowing about, generally keep the arm tips curved aborally in order to expose the terminal sensory podia. In the porcellanasterids the arms are rather rigid in most genera, but their distal end is then to some degree permanently aborally bent. The terminal ossicle, as noted, may be entirely dorsal to the arm end (the series of marginal plates); and if placed in a distal position, it is usually turned upwards at a more or less sharp angle, its dorsal

surface sloping upwards from the main dorsal line of the arm, its ventral surface being rounded, and the ambulacral groove extending upwards on its distal end. An optical cushion was not present in the porcellanasterids examined by MEURER in 1907 *(Thoracaster magnus (= T. cylindratus), Porcellanaster waltharii (= Eremicaster gracilis),* and *Porcellanaster vicinus (= Eremicaster v.))*.

The ventral skeleton in the interradial area consists as a rule of a pavement of squamiform plates, and similar plates may also extend ventrolaterally in the arms in a narrow band between the adambulacralia and inferomarginalia. These two latter series of skeletal elements in the arms, however, may also be separated only by a strip of naked integument, or they may be in immediate contact. The arrangement of the component plates in the ventrolateral (ventral interradial) areas may be rather irregular. Generally, however, the plates lie in fairly distinct tangential series, parallel to the margin where new plates are formed, and further they may form fairly regular "radial" columns parallel to the interradial line, extending from the marginalia to the adambulacral and oral ossicles, in *Hyphalaster* e. g., with two radial columns of ventrolateral plates, and in *Eremicaster* e. g., with about four such radial columns corresponding with a marginal plate.

The ventrolateral plates are often hardly visible even in dried specimens, being concealed by a thick and leathery skin. They may bear an armature of spinelets, and this is a general rule in some genera, as e. g. *Thoracaster*. In some species of other genera such an armature, however, can only be considered an individual variation.

An anal opening is absent in all porcellanasterids, and also an intestine is always lacking. The center of the disk, however, is often raised into a conical eminence or a long tubular appendage, which is frequently designated as an epiproctal appendage. A tail-like appendage – appearing as a subcylindroid tube – is thus typical of *Porcellanaster* and *Eremicaster;* but the possession of a distinct apical appendage or apical cone is otherwise primarily a juvenile feature, and it may be subject to highly individual diversity. The central dorsal area, also if a prominence is lacking, is generally distinguished by an armature of very small paxillae or spiniferous plates.

The presence of an apical appendage was first mentioned in the literature by E. PERRIER in 1882 with regard to his *Caulaster pedunculatus (= Porcellanaster cæruleus* juv.*)*. He called it the "pédoncule dorsal", and compared it to the stalk of the crinoids. SLADEN in 1883 p. 214, in his diagnosis of the porcellanasterids, mentioned it as: "A central epiproctal prominence, more or less defined, frequently developed into an elongate tubular prolongation."

WYVILLE THOMSON in his original description of *Porcellanaster cæruleus* (1877 p. 380) stated that: "the excretory opening is very prominent in the centre of the dorsal perisom of the disk," but, as SLADEN notes (1889 p. 130), this "inadvertent remark probably arose from the examination of a specimen in which the extremity of the epiproctal funnel was either invaginated or actually broken off." SLADEN also comments on PERRIER's above cited hypothesis regarding the "pédoncule dorsal," stating that it can have no morphological basis whatsoever, as the structure seems to him "to be nothing more or less than an extraordinarily developed anal funnel (whether aborted in function or not is immaterial for the present argument), and as such it is the homologue of the anal funnel of a Crinoid ...". Eventually PERRIER, in 1894 p. 201, compared and homologized the "pédoncule dorsal" to the ventral umbilical cord by which the juveniles of *Asterias spiralis* are attached to their mother animal, considering this – like the stalk of the crinoids – a modification of the praeoral lobe of the embryo.

SLADEN (1889 p. 129) says that: "Under favourable conditions, I have detected an extremely minute pore at the extremity of the tubular epiproctal prolongation in *Porcellanaster*. It is, however, so very small that I do not think it can act (in the adult at any rate) as an anal aperture, although it may probably be an excretory orifice," and p. 130 he notes "I have also found a similar pore at the extremity of the epiproctal peak in *Ctenodiscus,* and likewise in *Hyphalaster*." FISHER (1919 p. 42), in the description of three juvenile *Benthogenia cribellosa,* notes concerning the prominent apical appendage here that "there is certainly a tiny pore at the summit," but adds "whether this is confined to immature life can not be determined." The present author similarly thinks to have observed a pore in the apical cone of specimens of *Eremicaster vicinus,* (cf. p. 164). LUDWIG (1905 p. 98), however, states with regard to his *Porcellanaster waltharii (= Eremicaster crassus)* that he has convinced himself through dissection and serial sections, that the apical appendage is closed at the end. He found it encasing an extension of the coelome and divided by a longitudinal

mesenterial septum into two half tubes which at their bases were in wide open connection with the coelome. GOTO (1914 p. 96) when considering the apical appendage of *Ctenodiscus* notes that "In the centre of the conical abactinal prolongation one can easily distinguish in many specimens a small "pore" evidently connecting with the body cavity. This is also present in many *Eremicaster tenebrarius,* and is what SLADEN (GOTO, however, must here mean WYVILLE THOMSON) took to be an anus in *Porcellanaster*. I (GOTO) think it must be an artificial opening caused by a stretching of the abactinal membrane at the summit of the cone, and possibly subsequent wearing, as the rudimentary paxillae are usually more or less worn down here."

Since the porcellanasterids, besides lacking an anal opening, also lack any intestine, it is of course not strictly correct to speak of the tail-like dorsal appendage as an epiproctal appendage, and LUDWIG (1905 p. 90) therefore proposed naming it "Scheitelfortsatz" or "Apicalfortsatz" (in English version "apical appendage"), this being a more correct term as not hinting at any special function of the structure. HYMAN in her handbook (1957 p. 250) mentions that the structure is "of unknown significance". This is quite true, but some very probable guesses as to its function can be made, and, in fact, have been made. In the integument of the apical appendage or the apical cone is usually found a very crowded assemblage of minute calcareous deposits, similar in type but smaller than those of the main part of the disk, and this crowding of the skeletal elements in the preserved specimens is no doubt a consequence of that the organ has been strongly contracted. L. CUENOT in 1891 p. 385 mentioned the apical cone of the porcellanasterids immediately after having discussed the apical cone which can be raised temporarily in *Astropecten* as a possible tactile organ, since if it is touched this sea-star buries itself deeper down into the sand. Possibly CUENOT thus considers the apical cone of the porcellanasterids having the same function. MACBRIDE (1933 p. 402) also expressed the notion that the permanent cone of the porcellanasterids was a further development of the temporary elevation of the back of the astropectinids; not aware of the fact that already CUENOT had pointed out the homology. (Also the present author – before coming across the cited references – arrived at the obvious conclusion that the apical cone of the porcellanasterids was the homologue of the temporary cone in the astropectinids).

The apical appendage or cone is evidently capable of being much extended in the living animal; and, no doubt, a similar cone as in *Astropecten* may be raised also in those porcellanasterids in which no trace of a such is to be observed in the preserved specimens. Perhaps the apical cone or appendage in the porcellanasterids can be supposed to have a function also in keeping a channel open to the surface from their burrows (cf. p. 41). That the apical cone or appendage is relatively larger in the juveniles than in the adults, may be explained by such a function.

The dorsal armature of the porcellanasterids is somewhat varying in the different forms. In the juvenile specimens there is at first a pavement of rather large rounded perforated plates; but subsequently these become absorbed and replaced by the final skeleton, which may consist of plates, or of pseudopaxillae, or of paxillae.

The specimens described by PERRIER in 1882 under the name of *Caulaster pedunculatus,* and referred to above, were juveniles with an embryonic pavement of plates, which PERRIER homologized with the calyx of the crinoids, considering, as noted, the apical appendage homologous with the crinoid stem. PERRIER also noted that the possession of these plates was an embryonic character, and that they disappeared with age. SLADEN (1883 p. 217, 1889 pp. 130-131) rejects, however, the theory of the embryonic plates being homologous with the crinoid calyx and mentions as one of the things speaking against it that in *Porcellanaster* (and *Caulaster)* there is a dorsocentral plate, and it is with this plate alone "that any relationship with the stem of a Crinoid could exist in the apical system of an Asterid." PERRIER also compared the plates around the apical appendage of his *Caulaster* with those forming the periproct of an echinoid, but P. H. CARPENTER (1884) found that this comparison could not be maintained, as according to PERRIER's description the apical system of *Caulaster* consists, not of genitals and oculars (basals and radials) as in an echinoid, but of underbasals and basals, and SLADEN in 1889 notes that he entirely concurs with this view. However, with regard to the arrangement of the embryonic plates in the porcellanasterids, the present author agrees with LIEBERKIND, who, in 1935 p. 7, about the dorsal skeleton of juvenile *Porcellanaster cæruleus* stated that: "Whether these first rudiments of plates should be called basalia or radialia is a matter of judgment, they have no phylogenetic importance at all, and are only to be

considered a natural arrangement of rudimentary plates in a radially built animal."

The permanent dorsal skeleton which replaces the embryonic one, when this is absorbed, may also partly consist of rounded perforated plates, so e. g. in the arms of *Eremicaster*. In the disk area there may be minute spiniferous plates, at first few but in older specimens more numerous, e. g. in *Porcellanaster, Eremicaster,* and *Sidonaster,* and in some species of *Styracaster*. The dorsal skin in these forms appears thin and membraneous, especially if the animal is extended by a full stomach. In well expanded specimens, e. g. of *Eremicaster,* it can be observed that the dorsal integument is crisscrossed by bands of fibrous tissue, in the interspaces between which are found the plates and the papulae. In some well-preserved specimens e. g. of *Porcellanaster*, the skin which clothes the dorsal spinelets may be seen extending far off their distal point.

The dorsal armature of the adult specimens is composed of distinctly developed paxillae in the genera *Hyphalaster, Benthogenia, Lysaster, Thoracaster, Abyssaster,* and in some species of *Styracaster*. The paxillae usually are closely crowded, but may be somewhat spaced when the animal is well expanded. In expanded specimens the spinelets of the paxillar crown, which are movably attached to the shafts, may be seen bent horizontally outwards to meet their neighbours and thus protect the surface of the animal.

As to the microscopic structure of the skeletal elements reference is made to the descriptions and figures given by LIEBERKIND in 1932 and 1935. The larger calcareous components are generally robustly built, whereas the smaller components usually are of a very open structure, the embryonic plates, as mentioned above, being perforated and the spinelets usually composed of fine rods united by short transverse dissipiments.

The madreporic body is usually conspicuous, subcircular, and with deep furrows radiating from a point located near the adcentral margin, or stretching across in radial direction. It lies close to the marginal plates, touching these or being separated from them by a few rows of paxillae, its position being individually variable.

Papulae were recorded by SLADEN from the dorsal side of his *Porcellanaster caulifer* and his *P. gracilis (= Eremicaster g.)*. Generally, however, the papulae are very difficult to observe, only showing themselves when the disk is well expanded. And when in many porcellanasterids not mentioned, it does not necessarily mean that they are really absent in these. CUENOT is not right when stating, in 1948 p. 209, that papulae are wanting in the porcellanasterids. HYMAN (1955 p. 382) notes that "In the Porcellanasteridae, which mostly lack papulae, their place is presumably taken by the cribriform organs, assumed in the want of other evidence to have a respiratory function ..." ("The papulae constitute the usual respiratory provision of the asteroids but cannot be of supreme importance as they are few in number in many Phanerozonia and wanting in some cases").

The papulae are confined to the dorsal side of the disk proper, but are always absent from the central area and the radial lines in which the stomach is attached. They emerge singly in the interstices between the paxillae or plates and are usually not very numerous. In those porcellanasterids in which the paxillae are crowded and staggered, the papulae may be present, in the areas in which they occur, in a slightly larger number than that of paxillae; in a specimen of *Hyphalaster inermis* thus each paxilla in the papular area was surrounded by 5-6 papulae, and each papula enclosed by 3 paxillae. In the forms with spaced and non-staggered plates, the papulae are at most present in the same number as that of the plates, thus a specimen of *Eremicaster crassus* shows an equal distribution of spiniferous plates and papulae in the interradial papular areas.

Papulae were observed in specimens of all the genera represented in the present material, and so their occurrence is recorded now in all the genera of the Porcellanasteridae except *Lysaster* of which, however, only two specimens are known.

Pedicellariae are recorded from a single genus only, viz. *Porcellanaster* s. str. *(Caulaster, Albatrossia),* but they are not of a stable occurrence, some specimens possess them, others do not. They are known only from juvenile specimens and thus perhaps become lost with age. They are straight, sessile (simply two movable spines) and placed on the dorsal side, mostly interradially. Also the ambulacral spines in this genus *(Porcellanaster)* may in pairs form pedicellariae, one to each ossicle, and occasionally the oral spines may do the same.

The gonads are present in a number of ten, i. e. with a single one to each side of the interbrachial septa. (In some cases the gonad papillae were observable dorsally at the arm angles). Each gonad has the appearance of a small tuft of e. g. 6-10 unbranched or slightly branched tubules, usually 8-10 mm long at most; in e. g. a *Thoracaster cylindratus*

with R 103 mm up to 12 mm long. The gonads were examined in several specimens; and supposedly ripe eggs were found in specimens of *Hyphalaster inermis, Thoracaster cylindratus, Abyssaster tara,* and *Eremicaster crassus,* all from st. 238, in *Styracaster horridus* from st. 664, in *Eremicaster crassus* from st. 217, and in *Eremicaster gracilis* from st. 716. The eggs are roundish or slightly oval, and measure up to 0.5-0.6 mm. (Ripe eggs in porcellanasterids were recorded also by LUDWIG in 1905 from a specimen of his *Porcellanaster waltharii (= Eremicaster gracilis)).* Presumably, the porcellanasterids have a direct development, to judge from the egg-sizes when compared with those of other marine invertebrates of which the type of development is known (cf. THORSON 1952 pp. 282-283). Even when ripe, the gonads are not very voluminous, and the number of eggs contained in them is only small.

The tube-feet ampullae are single. (They were examined by LUDWIG (1905 pp. 91, 103) in *Hyphalaster moseri (= H. inermis)* and in *Porcellanaster pacificus (= Eremicaster p.)).* FISHER included this feature as one of the distinguishing characters in his diagnosis of the Porcellanasteridae. But it has since proved (FISHER 1919) that also the Goniopectinidae have single tube-feet ampullae. (The Astropectinidae and the Luidiidae have the tube-feet ampullae double). That the tube-feet ampullae in the porcellanasterids are single has been ascertained by the present author in specimens of all the examined genera.

The polian vesicles are present in a number of two in the interradius with the madreporite (with one to each side of the stone canal which is fused to the ventral body wall) and singly in the other interradii. (LUDWIG in 1905 recorded this arrangement of the polian vesicles from his *Porcellanaster pacificus* and *P. waltharii,* but stated that he did not find any polian vesicles in his *Hyphalaster moseri.* In the present study, however, polian vesicles were observed arranged as recorded whenever examined, also in specimens of *Hyphalaster inermis).* The stone canal is rather calcified and may be visible through the ventral integument, in *Porcellanaster* and *Eremicaster* e. g.

The stomach, which fills out the entire disk, consists in the porcellanasterids of a single undivided cavity which has the dorsal wall closely attached to the dorsal body wall. There is not the least trace of intestinal caeca. FISHER (1928) noted about *Thoracaster* that "There is no dorsal chamber of the stomach similar to that which is characteristic of most sea stars. Instead the dorsal wall is closely juxtaposed to the wall of the disk as in the Ophiuroidea"; and this description seems to fit every porcellanasterid. From the stomach extend in each arm the usual pair of pyloric caeca (hepatic c., radial c., or brachial c.), cf. fig. 10, pl. 4 in LIEBERKIND 1935, which shows a specimen of *Styracaster chuni* in which the dorsal body wall has been removed.

Parasites: The parasitic chaetopod *Myzostoma* has been found in the present material on specimens of *Hyphalaster inermis* from sts. 52 and 282 in the Atlantic and the Indian Ocean respectively, and on specimens of *Abyssaster tara* from st. 238 in the Indian Ocean. (KOEHLER in 1908 mentions tumors on his *Hyphalaster scotiae* as probably caused by an infection with *Myzostoma).* An Athecate Hydroid was commensalistic on some specimens of *Eremicaster gracilis* from the Panamic region (cf. p. 160). Dendrogate Ascothoracids, the internal crustacean parasites, were found in some dissected specimens of *Hyphalaster inermis* from sts. 30 and 52 in the Atlantic and from st. 282 in the Indian Ocean respectively; and in a specimen of *Eremicaster crassus* from st. 238 in the Indian Ocean. Also an *Eremicaster gracilis* from st. 716 in the Panamic region appears to be infected with these organisms. (FISHER in 1919 p. 35 recorded *Dendrogaster* from *Sidonaster vaneyi).*

Remarks on the supposed mode of life: The porcellanasterids – being phanerozoniate seastars – have an adambulacral peristome, which means that the most prominent skeletal parts of the frame surrounding the oral aperture centrally on the ventral side (mouth, actinostome) is formed by the five interradial jaws or pairs of oral ossicles, which again are connected by the radially situated circumoralia or "first vertebrae", composed of the fused first and second ambulacral ossicles, (fig. 3*c, d).* The skeletal frame around the mouth can be either constricted or widened to a rather considerable degree (the structure being articulated on the five primary oral ossicles). The oral membrane, or peristome, which is expanded between this frame is very dilatable, and, as seen from some specimens, can be distended into a wide funnel leading into the stomach. In case of full stomachs it may lie as a thin web over the stomach content. When FISHER in 1928 discussed the skeletal frame around the mouth of *Thoracaster,* he stated that the ambulacral elements here were longer than he had noted in any other sea-

star and that the whole frame was unusually flexible. He therefore concluded that fairly large objects could be ingested.

All porcellanasterids are mud-swallowers. Curiously enough, SLADEN in his report on the Challenger material did not make any references whatsoever to the fact that the stomach of these sea-stars is often found completely filled with mud. But it has repeatedly been noted by later authors. FISHER, op. cit., recorded in a *Thoracaster* (of which, however, no size was given) a stomach content of 9 ccm mud (with various organic matter as foraminiferans, diatoms and radiolarians). In the examined Galathea material e. g. an amount of 14 ccm mud was found in a specimen of *Styracaster horridus* with R/r 91/21 mm. The mud in the stomachs always contains many foraminiferans, calcareous and sandincrusted forms, and also radiolarians; in addition sometimes minute snails, and bits of worm tubes, and also sponge spicules and different parts of sea-urchin skeletons e. g. The latter elements, however, may have been taken as dead debris, and this of course may apply also to the other items mentioned. One small *Porcellanaster cæruleus,* R/r 11/4.5 mm, however, in its stomach had the remains of a comparatively large sea-urchin which it must have swallowed whole. The porcellanasterids thus may also act as scavengers and perhaps be facultative predators. Plant debris was found in some stomachs, e. g. a 23 mm long and 1 mm thick twig in a *Hyphalaster* with R about 65 mm.

Many sea-stars feed wandering about on the surface and by adhesion to the podia selecting and picking up organic matter, which then by coordinate movements of the podia is passed to the mouth; and e. g. the sand-dwelling *Astropecten* (a distant relative of the porcellanasterids), though it spends most of its time buried in the bottom, always ascends in order to feed.

The mud-swallowing porcellanasterids, on the contrary, most certainly do not leave their burrows for feeding. And since they can hardly be considered just swallowing the bottom material below them (which would be of small value as food), there is every reason to believe that they are able to secure from above the surface material comparatively rich in organic matter. The water circulation produced by the ciliate cribriform organs (cf. p. 41) therefore no doubt also serves in maintaining a constant flow of matter from the surface down to the sea-star so that it may be caught in the mucus secretion and subsequently led to the mouth by the podia. The distinct spineless lines which ventrally in the most spiniferous specimens of *Hyphalaster* extend from the cribriform organs to the furrow correspond to the ciliary grooves in *Ctenodiscus,* cf. p. 41.

In some stomachs much of the content was found in the form of minute balls of detritus-like substance, but though these might be considered swallowed food pellets formed by the podia, they rather are faecal pellets derived from the ingested bottom material, the deep-sea floor presumably being covered with faecal pellets in quantities. When the organic content in the swallowed material has been utilized the whole stomach content must be ejected through the mouth, and before feeding again the animal probably moves forward sufficiently to obtain the surface material from another place.

The porcellanasterids perhaps ascend regularly in order to change position and make a new burrow in another feeding place, or maybe they ascend only in order to spawn. The manner in which the porcellanasterids bury may reasonably be considered about the same as that of *Astropecten,* which is able to descend vertically (and rapidly), throwing the sand aside by outwards flings of the podia. In the porcellanasterids, however, perhaps also the furrow spines play a part in digging (which would explain their usually flattened shape, and perhaps their transformation into the so-called segmental organs in some genera). The porcellanasterids can no doubt also move about below the surface of the substratum. (At least, another of their distant relatives, *Luidia,* is able to glide, even surprisingly quickly, through the sand under its surface).

Some examined porcellanasterids with supposedly ripe or almost ripe gonads had their stomachs completely filled with bottom material, and so the periods of sexual activity probably have no influence on the feeding activity. The gonads even when supposedly ripe are also only small in relation to the animal. A greenish substance, the secretion from the pyloric caeca, may be found in otherwise empty stomachs.

The long-armed porcellanasterids often have the arms at different stages of regeneration, and so they are evidently easily broken in life, perhaps during burrowing, perhaps due to attacks by enemies.

The colour of the porcellanasterids usually is pale greyish or pale yellowish pink, or possibly reddish orange (or faint purplish), and with a darker (in *Porcellanaster* and *Eremicaster* dull bluish) cast on the disk when a possible stomach content shows through the thin skin; and with the cribriform organs light orange or yellowish.

On the taxonomic value of various characters, the ratio R/r, etc.: In the description of a sea-star the size is usually given as R/r = x/y mm, R being the distance from the center of the disk to the arm tips (i. e. the length of the entire arms, or rays, or radius of the specimen as a whole), and r the distance from the center of the disk to the interbrachial angle (the radius of the disk). It has also been customary to record the ratio R/r in the specific diagnosis, but this should be regarded with some caution since this ratio shows a definite increase with growth, in accordance with the positive allometric growth of the arms. The figures of R/r form a very useful means, however, for characterizing the different individuals from the same catch.

Owing to distortion of the specimens, it may sometimes be difficult to record R/r with only reasonable exactness. Furthermore, the measurements are influenced by the extent to which the stomach is filled, i. e. whether the mouth frame is widely opened or closely constricted, especially the measurements of r is influenced hereby, and in the present study the measurements therefore – in specimens with a widened mouth – were taken, not from the center of the disk, but from the proximal end of the mouth-spines. The length of R usually is slightly varying in the different arms of the same specimen; and in the long-armed forms, in the cases where some of the arms have been broken off and later regenerated, the arms may be of very different lengths, and it is then the length of the longest arm which is stated. The measurements given for R in the following text should therefore not be taken too strictly, some variation should be allowed for.

The accompanying diagrams (figs. 4-5) illustrate the change in the ratio R/r (the increase in relative arm length) with growth in some species of porcellanasterids of which a sufficient number of measurements are available (from records in the literature as well as from the Galathea material). In the diagrams the figures of R/r are indicated with R measured along the horizontal axis and r along with the vertical axis. Further, the diagrams illustrate the gradual increase in the number of superomarginal plates.

It will be seen that the rate of growth as expressed by the gradual change in the measurements of R/r, is the same in *Hyphalaster inermis, Thoracaster cylindratus, Abyssaster tara,* and *Porcellanaster cæruleus.* On an average the ratio R/r in these porcellanasterids is <2 in the juvenile specimens, about 2 by R 10-20 mm, about 2.5 by R 35 mm, about 3 by R 60 mm, and increasing to about 3.5 by R 70-100 mm. Approximately, the growth as expressed by the changes in R/r follows a straight line, in the just mentioned examples with a gradient of about $^1/_4$.

The increase in number of superomarginals with growth is about the same in *Hyphalaster inermis* and in *Thoracaster cylindratus,* though in the latter slightly on the high side of the variation found in the former. These two porcellanasterids also both have slender arms encased by the superomarginals. In *Abyssaster tara* and in *Porcellanaster cæruleus* the number of superomarginals is lower than in the former forms (in equal-sized specimens) and the increase in number slower, corresponding to the fact that the arms in *Abyssaster* and *Porcellanaster* are broader, not encased by the superomarginals, which also are relatively larger.

In *Styracaster horridus, Eremicaster crassus,* and *Eremicaster gracilis,* there is a faster increase in the ratio R/r with growth than in the above mentioned forms, R/r being about 2.5 by R 15 mm, about 3 by R 35 mm, about 4 by R 60 mm (and in *Styracaster horridus* increasing to about 5 by R ab. 125 mm), the growth gradient being about $^1/_6$. In these forms the disk is thus relatively smaller in relation to the arm length than was the case in *Hyphalaster inermis* and the other first discussed forms.

The number of superomarginals in relation to the arm length in *Styracaster horridus,* which has slender arms encased by the superomarginals, is the same as in *Thoracaster cylindratus.* In *Eremicaster gracilis* the number of superomarginals agrees with that found in *Styracaster horridus* and in *Thoracaster,* though in *Eremicaster* the arms are not encased by the superomarginals. In *Eremicaster crassus* the number of superomarginals is slightly lower on an average than in equal-sized *E. gracilis,* agreeing with the number found in *Hyphalaster inermis.*

In the other porcellanasterids the growth-rates as expressed by the ratio R/r and the number of superomarginals are as follows: *Hyphalaster hyalinus* and *H. scotiae* agree with *H. inermis. Abyssaster diadematus* and *A. planus* agree in the ratio R/r with *Abyssaster tara,* but apparently have a slightly larger number of superomarginals in relation to the arm length. *Styracaster caroli* and *S. elongatus* agree with *S. horridus,* whereas *Styracaster chuni, S. paucispinus, S. robustus, S. armatus,* and *S. spinosus,* all agree with *Hyphalaster inermis. Styracaster monacanthus* has the number of superomarginals corresponding to that which is found in *S. chuni,* but has a relatively larger disk and shorter arms, R/r being 2 by R 24 mm. *Benthogenia* and *Lysaster* too

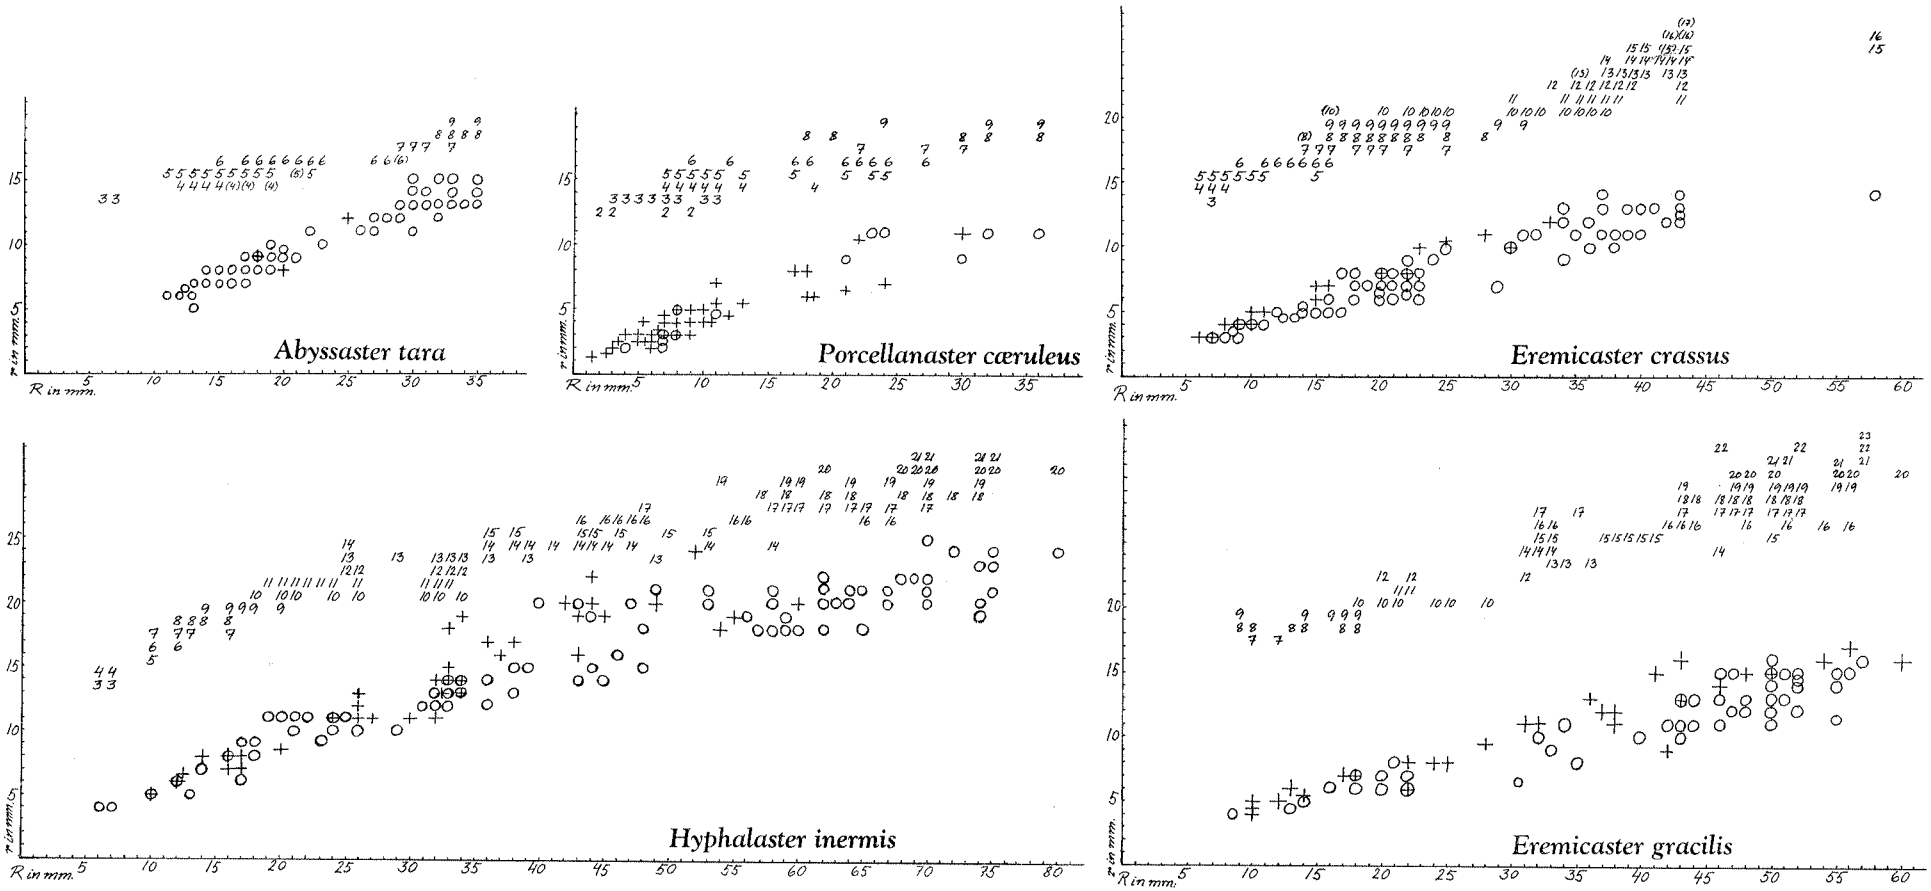

Fig. 4. Diagrams illustrating the rate of growth as expressed by the change in R/r and in number of superomarginals in *Abyssaster tara, Porcellanaster cæruleus, Hyphalaster inermis, Eremicaster crassus,* and *E. gracilis.* The horizontal axis gives the length of R, the vertical axis the length of r. Crosses refer to specimens recorded in the literature, circles to specimens in the Galathea material.

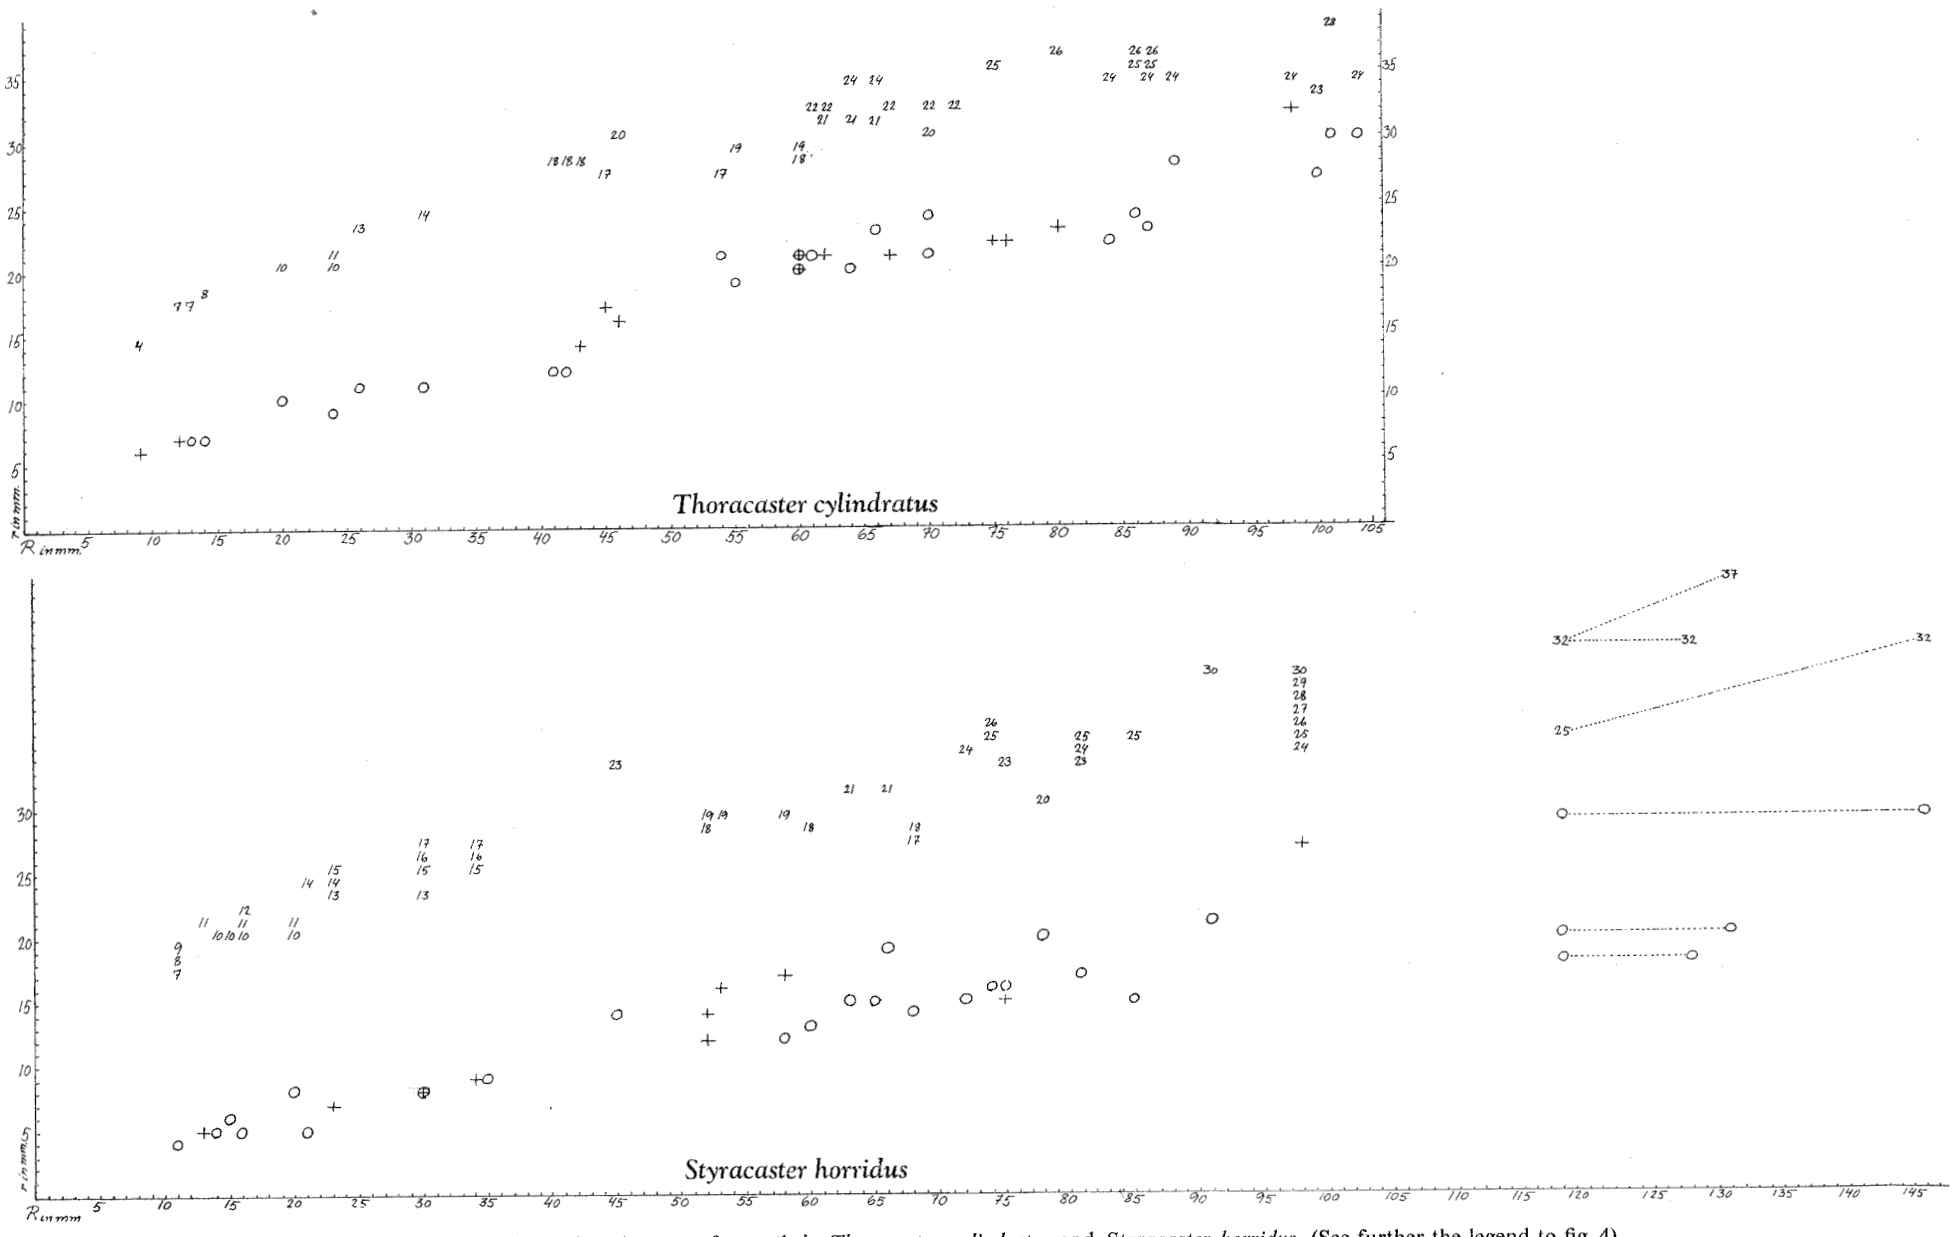

Fig. 5. Diagrams illustrating the rate of growth in *Thoracaster cylindratus* and *Styracaster horridus*. (See further the legend to fig. 4).

have a low ratio of R/r, about 2.6 in *Benthogenia* by R 78 mm (17 superomarginals) and about 2.3 in *Lysaster* by R 55 mm (11 superomarginals). *Eremicaster vicinus* and *E. pacificus* agree with *E. crassus,* and *Sidonaster* agrees with *Porcellanaster.*

The interbrachial arch (arm-angle or interradial part of the disk) may be curved inwards – in the forms with a large disk and narrow arms – if the stomach is empty, and outwards if the stomach is full. If the stomach is empty the ventral side usually slopes slightly downwards from the margin to the jaws with an inward-bending curve, but if the stomach is full the whole ventral side may be distinctly outwards curved. Similarly, the dorsal side (disk) may be flat, even depressed, if the stomach is empty; and the paxillae (if such occur) are then densely crowded; but if the stomach is full, the whole disk may be much inflated, and the paxillae are then spaced on the expanded integument. The shape of the body thus is of little or no value as a specific character.

Much information given in the descriptions or diagnoses of porcellanasterids in the literature is in fact of no specific significance, and is hardly of any individual significance either, since the descriptions concern specimens in a particular (preserved) state of contraction or expansion. Width of mouth opening, width of furrows, direction of furrow spines, position of marginals, perpendicular or arching over the disk, etc., are all characteristics which naturally change continuously in the course of the life rhythm of the animals. A number of other features used taxonomically previously, change with growth, e. g. the appearance of the dorsal skeleton, number and also form of the marginal plates besides their spine-armature, to some extent also the number of cribriform organs. All such characters should therefore be considered with caution.

During the present investigation it appeared that still other characters, previously considered of taxonomic value, may actually be so variable within the species that they can only with the greatest reservation be used for a specific discrimination; for instance the presence of absence of segmental organs, the number of dorsal arm spines, the state of the ventral armature, and in some cases the presence or absence of a ventrolateral skeleton in the arms.

The porcellanasterids in the available material are often in a rather poor condition, which is not surprising as these animals from the deep-sea may have spent hours in the trawl in the warm upper waters of the tropical sea before reaching the deck. The long-armed forms are seldom caught intact, some arms are nearly always lost, or found broken off in the content of the dredge; and since this is the general rule, it has not been found of any interest to call special attention to it in the descriptions, but it will clearly appear from the accompanying photographs.

Remarks on the genera recognized, their distribution and interrelationship: Up to this date 15 genera and 57 species of porcellanasterids have been named in the literature. The following revision resulted, however, in a division of the group into only 9 genera and less than 25 valid species. The Galathea collection consists, as noted above, of 469 specimens; and these fall into 11 species and 6 genera. None of the species are new to science.

Of the recognized genera, *Benthogenia, Lysaster,* and *Sidonaster*, belong to the bathyal zone, and appear in their regional distribution restricted to the region of the Indian Ocean inclusive of the Malay Archipelago.

All the other genera occur in the abyssal zone, and all of them (except the still undescribed *Vitjazaster)* are known to be widely distributed in the deep-sea. They are *Hyphalaster, Thoracaster, Styracaster, Abyssaster, Porcellanaster,* and *Eremicaster.*

The present author, as mentioned above, has been able to examine a fair number of the known forms of Porcellanasteridae, having had representatives of all genera except *Benthogenia* and *Lysaster* at his disposal. Furthermore, in the Galathea collections some populations have been represented by adequate series of individuals so that it has been possible to form a fair idea of the infraspecific variation.

Many sea-stars are known to be rather polymorphic, with short- and long-armed specimens, spiny and paucispine ones, or some with pedicellariae and others without, occurring side by side. Polymorphism also proved a pronounced feature in some of the forms of porcellanasterids now examined, and actually it is a quite remarkable infraspecific variation which has been found in some of the larger samples of single populations.

The cosmopolitan nature of several of the abyssal species of porcellanasterids was demonstrated through the direct comparisons of widely separated populations, which the Galathea material made possible.

The Porcellanasteridae constitute a rather homogeneous group, and all the forms are undoubtedly of a monophyletic origin. Two main groups may

be distinguished. The first group comprises *Benthogenia, Lysaster, Hyphalaster,* and also *Thoracaster,* which all show a similar general appearance and are distinguished only by such characters which do not seem to be very important in principle. These genera no doubt are the most primitive of the recent porcellanasterids, and *Benthogenia* then probably the most primitive of them all. *Styracaster* may be referred to this same group, though it is more specialized; and also *Abyssaster* should be ranged here, though showing some special features. The second group comprises *Porcellanaster* s. str., *Eremicaster,* and *Sidonaster,* which all resemble each other very much in general appearance. They have only a small number of cribriform organs, and may show a specialized furrow armature. Hence they may be considered phylogenetically younger than the former group, though perhaps not younger than *Styracaster* (and *Abyssaster).*

The presumably older abyssal genera, *Thoracaster* and *Hyphalaster,* comprise only a single and a few species respectively, and these show rather constant characters (i. e. the monotypic *Thoracaster,* and *H. inermis* which is the only species of *Hyphalaster* known in more specimens) while a younger genus as *Styracaster* comprises a larger number of species, and another young genus, *Porcellanaster,* constitutes an apparently monotypic, but polymorphic group.

On the presentation of the material: In the following descriptions of the Galathea material it has been attempted always to adhere to the same sequence of presentation, viz. size, marginal skeleton, cribriform organs, terminal ossicles, dorsal skeleton, a possible dorsal prominence and papulae, adambulacral, oral, and ventral skeleton, possible biological remarks and distribution. The same order has been followed in the summaries of the descriptions in the literature, in which also the often different terminology has been transcribed into that used in the present paper. It should in this way be fairly easy to find the reference to any character wanted, and to compare the different descriptions. The descriptions given of the genera supplement the diagnoses, but do not repeat information given there.

In the descriptions of the various samples it has been tried to avoid unnecessary repetitions of what may be common to all species of a genus. In spite of this, some descriptions at first sight may appear more lengthy than perhaps worth while. It has been found necessary, however, to treat several characters, especially the spine-armature, in detail so that the variation in individuals and in populations might be demonstrated, and in that way proof given of the various specific identifications, and also to avoid the doubt which might arise as to some characters, if no reference was made to them.

Attention has been paid to various abnormalities, since these might throw light on some specific interrelationships, and also because some nominal species have been based alone on e. g. irregularities in the arrangement of the marginal skeleton. Several of the present specimens showing individual variations might undoubtedly easily (and erroneously) have been described as representing new species, if they had been dealt with separately and not as members of populations represented by more individuals, e. g. the one-spined *Styracaster horridus,* (cf. p. 98), the *Hyphalaster inermis* with mirror-shaped furrow spines (cf. p. 69), or the *Eremicaster gracilis* with a ventrolateral spine-armature (cf. p. 158).

Key to the recognized genera of Porcellanasteridae

(The key considers the fully developed specimens only)

Page

1a. Superomarginals of either side of arm joining in the radial midline from about the fifth or sixth opposite pairs. Furrow narrow. Cribriform organs rather papilliform. A mouth-spine to each oral ossicle 2

2a. Superomarginals unarmed, or with small dorsal spines, forming a double row in the arms. Arms subcylindroid. Adambulacralia subrhomboid-subcrescentic, and with a continuous row of subequal furrow spines. Paxillae, or possibly pseudopaxillae on disk 3

3a. Mid-interradially a set of odd marginal plates. No larger superomarginal spines. Cribriform organs confined to the interbrachial marginals ..... *Thoracaster* 82

3b. Mid-interradially a marginal suture 4

4a. Superomarginals of arms unarmed, those of disk possibly with a small spine. Cribriform organs confined to the interbrachial marginals ..... *Hyphalaster* 56

Page

4b. Superomarginals of disk unarmed; but at least some of those of arms with a dorsal spine 5
5a. Cribriform organs confined to the interbrachial marginals ..... *Lysaster* 80
5b. Cribriform organs developed on all marginals clear to the terminal ossicle. *Benthogenia* 81
2b. Superomarginals with one or several, robust erect spines placed in the midline of the arms, from the first pair of joining plates and outwards. Arms possibly compressed. Adambulacralia of arms with a protruding adoral part with close-set furrow spines, and an aboral part with a single or a few isolated spines. Paxillae, pseudopaxillae or spiniferous plates on disk. *Styracaster* 92
1b. Superomarginals of either side of arm separate to terminal ossicle 6
6a. Two mouth-spines, i. e. one to each oral ossicle. Superomarginals unarmed. Furrow spines in a continuous series. Paxillae on disk. 3-7 papilliform cribriform organs .. *Abyssaster* 72
6b. A single mouth-spine to the combined pair of oralia forming a jaw. Superomarginals possibly with a dorsal spine. Adambulacralia with a protruding adoral part to which the furrow spines are confined. No suboral or subambulacral armature. Spiniferous plates or pseudopaxillae on disk 7
7b. A single large cribriform organ of a papilliform structure. Terminal ossicle subcrescentic ..... *Sidonaster* 165
7a. One or three cribriform organs of a lamelliform structure. Terminal ossicle rather tubercular 8
8a. Three cribriform organs ..... *Eremicaster* 143
8b. One cribriform organ ..... *Porcellanaster* 123

The genus *Vitjazaster* Belyaev (in press), which in this key would be placed besides *Abyssaster,* has a set of odd marginal plates mid-interradially, where all other porcellanasterids, except *Thoracaster,* have a suture. It is further distinguished from all other porcellanasterids hitherto described by having paxillae also ventrally.

SYSTEMATIC PART

Hyphalaster Sladen, 1883, emended

Type-species: *Hyphalaster hyalinus* Sladen, 1883.

Diagnosis:

Porcellanasterids with superomarginals forming a complete casing to arms, unarmed, but those of disk possibly with a dorsal spinelet. A mid-interradial suture. Cribriform organs (5-11) confined to disk marginals.

Description:

The specimens of this group have a subpentagonal disk with the arms well set off, subcylindroid, of a rather uniform thickness throughout, and with the terminal ossicle placed rather distally, forming a blunt end, armed with 3, occasionally 5 spines. The cribriform organs are papilliform. The inferomarginals of the arms are only slightly lower than their superomarginal companions. The body is flat when the stomach is empty, the perpendicularly placed interbrachial marginal plates deciding its height, but even when the stomach is full the shape of the body usually do not become pronouncedly tumid. The genus is known to attain a size of R about 90 mm. The proportion of R to r ranges from hardly 2 in juvenile specimens to somewhat more than 3 in large ones. The dorsal side is armed with close-set, well-developed paxillae, or with pseudopaxillae or spiniferous plates. Juvenile specimens show an apical appendage, medium-sized specimens generally show a more or less distinct apical cone, while larger specimens are often devoid of any central prominence. The jaws show a well prominent broad rounded keel formed by the interradial and greater part of the two oral ossicles, which meet proximally and medially, being separated by a wide suture between the two places of contact. Distally the triangular surface of the primary oral ossicle is well exposed. There are 5-12 marginal oral spines, the proximal one the largest, the others subequal to the furrow spines. The adambulacralia have a subrhomboid to subcrescentic contour, and bear 3-6 furrow spines. All the furrow spines are connected

by a well-developed basal web, and form a continuous wavy series along the narrow furrow, which may be almost completely closed in by the overarching adambulacralia. The ventrolateral area is rather wide and paved with imbricating transversely elongate plates, arranged in tangential and in radial rows, which latter correspond two and two with the adjoining marginal plates. A narrow strip of small ventrolateral plates may also extend a varying distance down the arms. The ventrolateral plates are typically spiniferous, and also the surface of the oralia and the adambulacralia bear spinelets in the grown-up specimens. There is a fairly thick integument ventrally, and the contours of the jaws, adambulacralia, and ventral plates therefore are often more or less indiscernible.

Remarks:

SLADEN in 1883 erected the genus *Hyphalaster* to embrace his four species: *hyalinus, diadematus, inermis* and *planus,* and later the following other species (or nominal species) have been ascribed to the same genus, viz. *parfaiti* and *antonii* by PERRIER in 1885, *tara* by WOOD-MASON & ALCOCK in 1891, *valdiviae* by LUDWIG in 1900 (in CHUN), *moseri* by LUDWIG in 1905, *fortis, gracilis,* and *scotiae* by KOEHLER in 1907 (*a* and *b*), and *giganteus* by MACAN in 1938.

The form from the Valdivia Expedition which CHUN in 1900, p. 490, listed as *Hyphalaster valdiviae* n. sp. (on basis of LUDWIG's preliminary identification of it) was in reality a specimen of SLADEN's *Thoracaster cylindratus* (according to LUDWIG in 1907); and also the *Hyphalaster* n. sp., which RICHARD in 1903, p. 66, mentions from a Princesse Alice dredging, was a *Thoracaster cylindratus,* as it appears from the final report on the Princesse Alice material by KOEHLER in 1909*b*.

The other forms (not all specifically valid, as will be discussed in the following) fall into two groups as to the appearance of the arms. In one group the superomarginal plates join their opposites along the dorsal midline of the arms from about the fifth or sixth plates, whereas in the other group they all remain separate to the terminal ossicle. These two groups must be considered generically different. The former group, for which SLADEN's generic name *Hyphalaster* must be retained, comprises SLADEN's species *H. hyalinus* (the type-species), and his *H. inermis,* and further all later described species except *H. tara.* The latter group, for which the name *Abyssaster* is created, comprises besides WOOD-MASON & ALCOCK's *H. tara,* which is designated as the type-species of the genus, also SLADEN's *H. diadematus* and *H. planus.*

The group *Hyphalaster* s. str. is recorded from dredgings in all three oceans; and several individuals have often been obtained in a single catch. SLADEN's two species, *hyalinus* and *inermis,* were both from the Pacific and appear well distinct. PERRIER's *parfaiti* was from the Atlantic, but, as will be demonstrated in the following, it is evidently the same species as *inermis.* LIEBERKIND (1932 and 1935, in two of the more recent papers on porcellanasterids) discussed the Atlantic records of *Hyphalaster* in detail, and arrived at the conclusion that they all belonged to one and the same species, which he listed as *H. parfaiti,* and of which then *antonii, fortis* and *gracilis* are considered synonyms. The remaining species of *Hyphalaster* s. str., not discussed by LIEBERKIND, are besides the type-species *hyalinus: H. inermis, H. moseri, H. scotiae,* and *H. giganteus. H. inermis* includes, as noted, in the present authors opinion, *parfaiti,* further also *moseri,* and perhaps also *giganteus.* Thus only three valid species of *Hyphalaster* s. str. may be known at present, viz. *H. hyalinus, H. inermis,* and *H. scotiae.*

The Galathea Expedition obtained specimens of *Hyphalaster* s. str. in altogether 15 of the 27 dredgings yielding porcellanasterids (five in the Atlantic, eight in the Indian Ocean, and two in the south-western Pacific). All these specimens appear to belong to one and the same species, which is recorded here under the name of *H. inermis.*

Key to the species of *Hyphalaster* s. str.

Hyphalaster hyalinus Sladen, 1883

SLADEN 1883 pp. 235-237, 1889 pp. 156-159, pls. 26_{1-6}, 28_{13-16}.

This species was described from two specimens dredged at the Challenger st. 274 in the tropical mid-Pacific (7°25'S, 152°15'W, 5030 m, radiolarian ooze, 1.7°C.).

The type-specimen has R/r 20/10 mm; 8 superomarginal plates, joining their opposites from no. 6, and the two innermost to each side of the interradial suture with a dorsal, horizontally directed spinelet; proximal marginalia twice as long as high, distal ones higher than long; 7 narrow cribriform organs. Fairly large tumid terminal ossicle with 3 spines. Disk with spiniferous small plates (spicules) and pseudopaxillae with up to 4 spinelets; no apical cone. Adambulacralia subcrescentic, with 3 furrow spines (4-5 are shown in fig. 2 pl. 26) and 3-5 spinelets on their surface (18 adambulacralia according to the figure). Oralia with 6 marginal spines, and suborally about 3 spines along the suture and some few granules distally. Ventrolateral area with a plating of imbricating subhexagonal scales, each with 2-3 or a few more granules. A narrow strip of ventrolateral plates extending to the terminal ossicle.

The other specimen has R/r 12/15 mm, and, judging from fig. 4-5 pl. 26, 8 unarmed superomarginalia, 11-12 adambulacralia, all with naked surface, and also bare ventrolateral scales. A complete embryonic dorsal plating of scales. No apical appendage.

The type-specimen apparently is rather expanded due to a full stomach, and this partly accounts for SLADEN's description of the dorsal membrane as thin and almost transparent, and of the pseudo-paxillae as being well spaced. SLADEN (1889 p. 159) notes that he is not quite sure of the specific identity of the juvenile specimen, but probably there is no reason why this should be doubted.

H. hyalinus is distinguished by the dorsal spinelets on the interradial superomarginal plates, and by the dorsal armature of spiniferous plates and pseudopaxillae. Also the shape of the proximal superomarginalia, twice as long as high, may distinguish *H. hyalinus* from *H. inermis*, in which the proximal superomarginalia are generally subquadrate. In *H. hyalinus* the ventrolateral plates extend to the terminal plate, whereas in similar-sized specimens of *H. inermis* they usually extend only a short distance outside the disk area.

non: *H. parfaiti*, ALBERT 1902 p. 962, and RICHARD 1902 p. 86, = *Albatrossaster richardi* Koehler, 1909 (a juvenile *Porcellanaster cæruleus*).

SLADEN's description of *H. inermis* was based on two specimens from the Challenger st. 237 off Japan (34°37'N, 140°32'E, 3430 m, blue mud, 1.8°C.). The type-specimen has R/r 20/8.5 mm; 9 superomarginalia, joining from the 5th opposite pair, proximal ones subquadrate; 7 cribriform organs. Fairly large, somewhat tubercular terminal ossicle with 3 short spines. Dorsal side with closely crowded small paxillae with 5-10 spinelets. (See also p. 71). An apical cone. Adambulacralia with 3-4 furrow spines, and the proximal subrhomboid ones with a single subambulacral granule adorally. Oralia with 7-8 marginal spines (fig. 6 pl. 28 only shows 6), and 1-2 suboral granules. Ventrolateral plates subhexagonal and with 4-5 granules. No ventrolateral plates in arms. The other specimen has R/r 10/5 mm, and 5 superomarginalia. Several specimens were taken in the haul, according to the summary of the scientific results of the expedition.

H. moseri: The only other Pacific record of *Hyphalaster* s. str. hitherto (besides those of *H. hyalinus* and *H. inermis* just mentioned) is that of two specimens from the Albatross st. 3684 in the mid-Pacific (0°50′N, 137°54′W, 4504 m, globigerina ooze) on which LUDWIG (1905) based his species: *H. moseri.* They have R/r 26/12 and 32.5/13 mm respectively; 10 and 11 superomarginalia, joining their opposites from nos. 5-6; 9 cribriform organs. Terminal ossicle with 3 spines. Dorsal side with close-set paxillae with 6-8 spinelets. An apical cone. Adambulacralia with 4 furrow spines (in arms 3) and 3-4 subambulacral spinelets. Oralia with 7 marginal spines, and suborally 2-3 spines along sutural and some minute spinelets along distal margin. Ventrolateral plates with 4-6 spinelets.

LUDWIG noted that this new species was nearest to SLADEN's *inermis,* but distinguished by a richer ventrolateral and oral armature. When, however, the larger size of LUDWIG's specimens is considered, this difference (apparently the only one) is of no importance. It therefore seems reasonable to regard *H. moseri* as a synonym of *H. inermis.*

H. giganteus: In the Indian Ocean only a single specimen of *Hyphalaster* s. str. has hitherto been recorded, viz. by MACAN (1938) who described it as representing a new species, *H. giganteus,* though at the same time noting its close affinity to the Atlantic *H. parfaiti.* It may be merely an individual variation of this form (= *H. inermis*), and will be discussed in more detail on a following page.

H. parfaiti: This species was described by PERRIER (1885, 1894) from a single specimen dredged by the Talisman in the Bay of Biscay (st. 135 – by a lapse PERRIER in 1885 writes st. 138–: 46°09′N, 9°16′W, 4787 m, grey-yellow mud). The unique type has R/r 55/19 mm; 16 superomarginalia, joining their opposites from nos. 5 (-6), slightly longer than high; 9 cribriform organs. Terminal ossicle fairly small and with 3 short spines. Dorsal side uniformly covered with small paxillae with 7-9 granules. A faint apical cone. Adambulacralia subrectangular, with 4 flattened subequal furrow spines, and usually an irregular row of 5-6 slender subambulacral spinelets along the interradial margin. Oralia with 7-8 marginal spines, and with 3 fairly large spines along the suture, and about 10 smaller ones over the rest of the surface. Ventrolateral plates transversely elongate and generally with 5-7 spinelets, sometimes in two parallel rows.

It appears that this specimen is distinguished from the type of *H. inermis* merely by a richer spine-armature, a difference which is accounted for by its larger size.

H. antonii: E. PERRIER (1885, 1894) described this form from a single specimen from a Talisman dredging near the Azores (st. 131: 38°38′N, 27°26′W, 2995 m, soft white mud). It has R/r 16/7 mm; 9 superomarginalia, joining their opposites from no. 5; 7 cribriform organs, the two outermost ones rudimentary. Terminal ossicle with 3 short spines. Dorsal side with numerous small paxillae with 4-5 granules. A small apical appendage. Adambulacralia rather rectangular, with 4 furrow spines, and 1-3 subambulacral spinelets. Oralia with 8 marginal spines, and 3-4 granules on their surface. Ventrolateral plates subhexagonal and with 4-5 spinelets.

LUDWIG (1907 p. 313 foot-note) states that he considers PERRIER's *H. antonii* a juvenile *H. parfaiti.*

Under the name of *H. antonii,* KOEHLER (1909 *b* p. 29) records two specimens of *Hyphalaster,* R/r 14/8 and 16/8 mm, from two Princesse Alice dredgings at the Cape Verdes and off the Canary Islands respectively (st. 1150: 16°12′N, 24°44′W, 3890 m, sand and mud, and st. 1789: about 31°06′N, 24°00′W, 5413 m, globigerina ooze?). KOEHLER is inclined to think, however, that LUDWIG is right in supposing *H. antonii* to be a juvenile *H. parfaiti,* but considers it impossible to say definitely so without knowledge of intermediary stages. The specimen from st. 1150 belongs to the lot which Prince ALBERT in 1902 mentions as *Hyphalaster* sp.

LIEBERKIND (1935), after having re-examined the type-specimen, confirmed that *H. antonii* was identical with *H. parfaiti.* But something has gone wrong when he writes, p. 20, that "The number of adambulacral spinelets, of marginal plates as well as of madreporic plates, is on the other hand exactly the same in the two forms. Therefore, there is no doubt that LUDWIG is right in supposing that *Hyphalaster Antoni* only is to be considered an immature stage of *Hyphaloster parfaiti.*" – The juvenile stage, of course, shows a smaller number of superomarginals than the adult, and both stages only a single madreporite, as have all porcellanasterids, so, what LIEBERKIND wanted to point out perhaps was that the appearances of these structures were the same in both forms.

H. fortis: This species was described by KOEHLER (1907, 1909 *b*) from two specimens from the Prin-

cesse Alice st. 1150 at the Cape Verdes (16°12′N, 24°44′W, 3890 m, sand and mud) – by Prince ALBERT in 1902 p. 963 listed as *Hyphalaster* sp. –, and further KOEHLER recorded some arm-fragments from the Princesse Alice st. 753 near the Azores (about 30°50′N, 18°W, 4360 m, globigerina ooze). The two specimens have R/r 60/20 and 54/18 mm respectively; 19 superomarginalia, joining their opposites from nos. 5-6, (proximal ones described as about twice as high as long, see further p. 62, those of the arms as subquadrate); 9 cribriform organs. Terminal ossicles with 3-5 spines. Dorsal side with a uniform covering of close-set paxillae with a circle of granules surrounding about 10 central ones. The smaller specimen with an apical cone. Adambulacralia subrectangular, with 4 furrow spines and 3-4 subambulacral spinelets along interradial margin. Oralia with 10 marginal spines, and 3 small conical spines along the suture. Ventrolateral plates in tangential series, polygonal and with scattered granules.

KOEHLER (1921) records two additional specimens of *H.fortis* from the Princesse Alice st. 2986 in the Bay of Biscay (45°07′N, 7°06′W, 4870 m).

LIEBERKIND (1935 p. 19), after a re-examination of some arm-fragments of the original specimens, concluded that *H.fortis* was merely a synonym of *H.parfaiti.*

H.gracilis: KOEHLER (1907, 1909*b*) described this species from three specimens dredged by the Princesse Alice west of the Canary Islands (st. 1787: 31°07′N, 24°03′W, 5413 m, globigerina ooze). They have R/r 32/14, 33/15 and 36/17 mm respectively; 12 superomarginalia (-14 according to LIEBERKIND 1935), joining their opposites from no. 5, (proximal ones described as much higher than long, see further p. 62, those of arms as only slightly higher than long); 9 cribriform organs. Terminal ossicle conspicuous, with 3 spines. Dorsal side with close-set small paxillae. The medium-sized specimen with an apical appendage, the others without. Adambulacral ossicles subrectangular, with 4 furrow spines. (According to LIEBERKIND (1935), who had re-examined one of the original specimens, there may also be a few subambulacral spinelets, whereas KOEHLER stated that he did not find any). Oralia with 7-8 marginal spines, and 8-9 suboral ones, 3 of these conical and placed along the suture. Ventrolateral plates with granules.

KOEHLER (1921) records an additional specimen of this form taken by the Hirondelle II west of the Canary Islands (st. 3223: 30°50′N, 25°43′W, 5300 m).

LIEBERKIND (1935) concluded that *H.gracilis* was specifically identical with *H.parfaiti.*

Hyphalaster parfaiti is the name under which the more recent authors have recorded the Atlantic specimens of *Hyphalaster:*

LIEBERKIND (1932) recorded 14 and 12 specimens respectively from two Valdivia dredgings in the Gulf of Guinea (st. 56: 3°10′N, 5°28′E, 2278 m, blue mud, 3.3° C; and st. 63: 2°00′N, 8°04′E, 2492 m, 2.6° C.), ranging in size from R/r about 33/14 to 49/20 mm (e.g. 32/18, 34/14, 34/19, 37/16, 42/20, 43/19, 45/20, and 45/52 mm); number of superomarginals e.g. 13 by R 34 mm, 14 by R 41 mm, and 16 by R 47 mm; 7-9 cribriform organs.

LIEBERKIND (1935) further recorded *H.parfaiti* from two Ingolf dredgings: southeast of Greenland (st. 20: 58°20′N, 40°48′W, 3190 m, 1.5° C., 5 specimens), and in the southern Davis Strait (st. 37: 60°17′N, 54°05′W, 3230 m, 1.4° C., from which catch 30 specimens are present). The Ingolf specimens range in size from R/r 16/8 to 52/24 mm (e.g. 26/11, 26/13, 32/14, 38/17, and 45/19 mm); number of superomarginals e.g. 11 by R 26 mm, 14 by R 38 mm, 15 by R 46 mm, and 16 by R 43 mm; 7-9 cribriform organs.

A. H. CLARK (1948) recorded 7 specimens of *H.parfaiti* taken by the Atlantis in the mid-North Atlantic (st. 15: 35°17′N, 30°51′W, 3200 m); R/r 17/7, 17/8, 27/11, 30/11, 33/14, 34/13, and 34/14 mm; 5-9 cribriform organs.

MADSEN (1951) recorded the species from two dredgings of the Swedish Deep-Sea Expedition (on board the Swedish Albatross): In the tropical mid-Atlantic (st. 342: about 1°N, 18°40′W, 5250-5300 m, globigerina ooze, 2.3° C., 19 specimens), and in the tropical West-Atlantic (st. 357: about 2°25′N, 39°24′W, 4474-4430 m. calcareous clay, 1.3° C., 3 specimens). These specimens range in size from R/r 12/6 to 43/16 mm, (e.g. 12.5/6.5, 24/11, 32/11, and 32/14 mm), and have 5-11 cribriform organs. The smallest specimen has 6-7 superomarginalia.

The fairly large number of specimens available from some populations gave LIEBERKIND a fair knowledge of the infraspecific variation, and from this and a re-examination of several of the previously described specimens of *Hyphalaster,* he arrived at the conclusion – as already mentioned above – that all Atlantic specimens of *Hyphalaster* hitherto recorded, belonged to one and the same species, first described by PERRIER in 1885 under

the name of *Hyphalaster parfaiti*. LIEBERKIND (1935 p. 21) thus states: "Altogether the genus *Hyphalaster* seems to be a genus, in which the specific characters are rather vague; a thorough and critical revision not only of the forms from the Atlantic, but also of those from the Pacific is very desirable, but this is unfortunately beyond the scope of this work."

It is very regrettable that LIEBERKIND did not also discuss his material in relation to the forms of *Hyphalaster* described from the Pacific, so that it is unknown what characters, if any, he would consider of specific value in distinguishing between these different named forms. – The present author considers it impossible to distinguish the Atlantic *H.parfaiti* from Sladen's *H.inermis* from the Pacific, and the supposed vagueness of specific characters merely indicating that the various nominal species were described on the basis of characters of no specific value.

LIEBERKIND (1935) gave illustrations of the variations in shape of different specimens (different proportions of R to r was the main character for distinguishing some of the described "species"). He pointed out that the shape may vary a good deal in the individuals and that further the preservation is of some consequence. (As emphasized above the ratio R/r also always changes gradually with age due to the positive allometric growth of the arms, cf. the diagram fig. 4 p. 52).

LIEBERKIND (1935 p.22) mentions that: "Papulae are only to be found in the distal part of the radial region of the paxillae area." Since, however, the papulae never occur in the actual radial lines, it is the distal part of the disk area to both sides of the radial lines which is meant. None of the previous authors had observed papulae in *Hyphalaster*.

The number of oral and suboral spines were found by LIEBERKIND to be very variable. In some of the specimens from off Greenland he found some "rather coarse granules which nearly resemble short spines" along the border of the marginal plates, and most numerous on those next to the extreme cribriform organ.

The Galathea material:

The Atlantic:

St. 24. 3°54′N, 8°22′W, 3200 m, 2.7°C., clay. 4 specimens.

St. 30. 0°42′N, 5°59′W, 5160 m, 2.2°C., clay. 17 specimens.

St. 52. 1°42′N, 7°51′W, 2550 m, ca. 3°C., muddy clay. 17 specimens.

St. 65. 2°17′S, 8°10′E, 2770 m, 3.0°C., bluish clay. 1 specimen.

St. 99. 8°40′S, 11°10′E, 2690 m, 3.9°C., yellowish clay. 5 specimens.

The Indian Ocean:

St. 186. 32°33′S, 32°01′E, 3620 m, 1.2°C., globigerina ooze. 1 specimen.

St. 192. 32°00′S, 32°41′E, 3530 m, 1.1°C., globigerina ooze. 1 specimen.

St. 193. 32°34′S, 31°52′E, 3680 m, 1.1°C., globigerina ooze. 12 specimens.

St. 234. 5°25′S, 47°09′E, 4820 m, 1.4°C., (globigerina ooze?). 1 specimen.

St. 238. 3°23′S, 44°04′E, 3960 m, 1.8°C., globigerina ooze. 12 specimens.

St. 280. 1°56′N, 77°05′E, 4350 m, 1.3°C., globigerina ooze. 2 specimens.

St. 281. 3°38′N, 78°15′E, 3310 m, 1.8°C., globigerina ooze. 1 specimen.

St. 282. 5°32′N, 78°41′E, 4040 m, 1.5°C., blackish mud. 32 specimens.

The Pacific:

St. 664. 36°34′S, 178°57′W, 4540 m, 1.1°C., brown sandy clay with pumice. 2 specimens.

St. 668. 36°23′S, 177°41′E, 2640 m, 2.0°C., clay. 1 specimen.

The Galathea material of *Hyphalaster inermis* from each of the three oceans is treated separately in the following, since the specimens hitherto recorded from the Atlantic and the Pacific were formerly regarded as representing several species. There can be no objection to the identifying of the present Atlantic specimens, all from the region of the Gulf of Guinea, with the form named *H.parfaiti* by LIEBERKIND, and the description of the materials from the Indian and the Pacific oceans thereafter will demonstrate the specific identity of the whole lot.

The Atlantic specimens. (Figs. *6a-f, o, r, t; 7n, q-s, u-v.* Pl. I):

A total of 44 specimens of *Hyphalaster* s.str. were collected in the Atlantic. The four specimens from st. 24 have R/r 6/4, 12/6, 62/21, and 64/21 mm. The 17 specimens from st. 30 have R/r 7/4, 10/5, 14/7, 17/9, 19/11, 21/10, 22/11, 24/11, 25/11, 38/15, 40/20, 41/16, 43/20, 44/15, 44/19, 47/20, and 49/21 mm. Five of the 17 specimens from st. 52 have R/r 18/9, 21/11, 23/9, 29/10, and 32/12 mm, nine others have

R measuring from 38 to 49 mm, and three have R/r 60/20 mm. The single specimen from st. 65 has R/r: 48/18 mm. The five specimens from st. 99 have R/r 10/5, 18/9, 57/18, 58/21, and 59/19 mm.

The ratio R/r is less than 2 in the smallest specimens, 2 in those with R about 10-20 mm, and then on an average it gradually increases to 3 in the largest specimens, with R about 60 mm. As it will appear from the measurements recorded, and from the accompanying photos pl. I, the ratio R/r may be very varying in otherwise equal-sized specimens.

The numbers of superomarginal plates and of cribriform organs are the following:

R	Number of superomarginals	Number of cribriform organs
6-7 mm	3-4	3-5
10 mm	6-7	5-7
12 mm	7-8	7
14 mm	8-9	8-11
17-18 mm	9-10	7-9
19-24 mm	11	9-11
25-29 mm	12-13	7-9
32-41 mm	14	7-11
43-49 mm	14-15	7-11
48-57 mm	17	7-11
58-62 mm	17-18	7-9
64 mm	19	9

The superomarginal plates in general join those of the opposite side of the arms from nos. 5-6. In the two smallest specimens, R/r 6/4 mm (fig. 6*a-c*) and 7/4 mm (pl. I, 13), with still only 3-4 superomarginals, these are then separated for the whole length of the arms. In the population from st. 30 also the sixth pair of opposite superomarginals tend to remain separate, and actually the opposite superomarginals in some arms of these specimens do not meet until plates no. 7. The superomarginals thus remain separate to the terminal ossicle in a specimen with R/r 10/5 mm (pl. I, 11), although 6-7 superomarginal plates are present; and a single specimen, R/r 24/11 mm, is remarkable in having the superomarginals separate in some arms as far as to the 7th or 8th pair of plates. (Pl. I, 5).

The superomarginal plates of either side of the arms in general correspond exactly with each other, but they may also alternate to a varying degree, and they may be differently arranged in the different arms of the same specimen. One, or more often two superomarginal plates are situated below the terminal ossicle, and are hence triangular. The superomarginals of the disk are subquadrate, or, in large specimens, somewhat longer than high. The more distal of the superomarginals may be higher than long, often markedly so in the small specimens, less pronouncedly in the large ones. KOEHLER (op. cit.) described the proximal (disk) superomarginals of his specimens of *H.fortis* and *H.gracilis* as much higher than long, but this may be due to the fact that he has only considered the naked surface of the plates, and disregarded the parts covered by the cribriform organs. The superomarginals of the arms sometimes have the proximal margin slightly concave and the distal margin correspondingly excave, so that the vertical sutures appear as curved lines with the concavity directed towards the tip of the arms (fig. 6*t*).

The inferomarginal plates typically lie exactly below their superomarginal companions, but may also subalternate with these. They are of the same number as the superomarginals, or maybe one or two more. The small specimen from st. 30, with R/r 7/4 mm, has up to 5 inferomarginals together with 3-4 superomarginals. The inferomarginals are in the proximal part of the arms slightly lower than their superomarginal companions, but towards the end of the arm they decrease relatively more in height than do these, and distally the difference in height thus becomes more pronounced.

A few specimens have proximally in the midline of one or more of the arms, for a stretch of up to 3 superomarginals, a series of small rounded secondary plates, e.g. two specimens from st. 52 with R. 18 and 45 mm, and two specimens from st. 30 with R. 19 and 49 mm. (Fig. 6*t*).

The most proximal marginal arm plates in the large specimens may carry some granular spinelets along the vertical margins, especially along the aboral one. Generally, however, the plates are completely naked (except for the papillae of the cribriform organs).

The cribriform organs are only just developed in the juvenile specimen with R/r 6/4 mm (st. 24). The largest number is here 3 in each interradius, and they are most distinct in the interradius with the madreporite, whereas they are hardly discernible in the other interradii, being quite rudimentary, with only a single series of papillae to each side of the vertical sutures, and not yet extending the whole way to the ventral side (figs. 6*a-b*). In the specimen with R/r 7/4 mm (st. 30) there are 3-5 cribriform organs in each interradius, also yet all rudimentary. In the two specimens with R/r 10/5 mm, the number of cribriform organs is 5 in that from

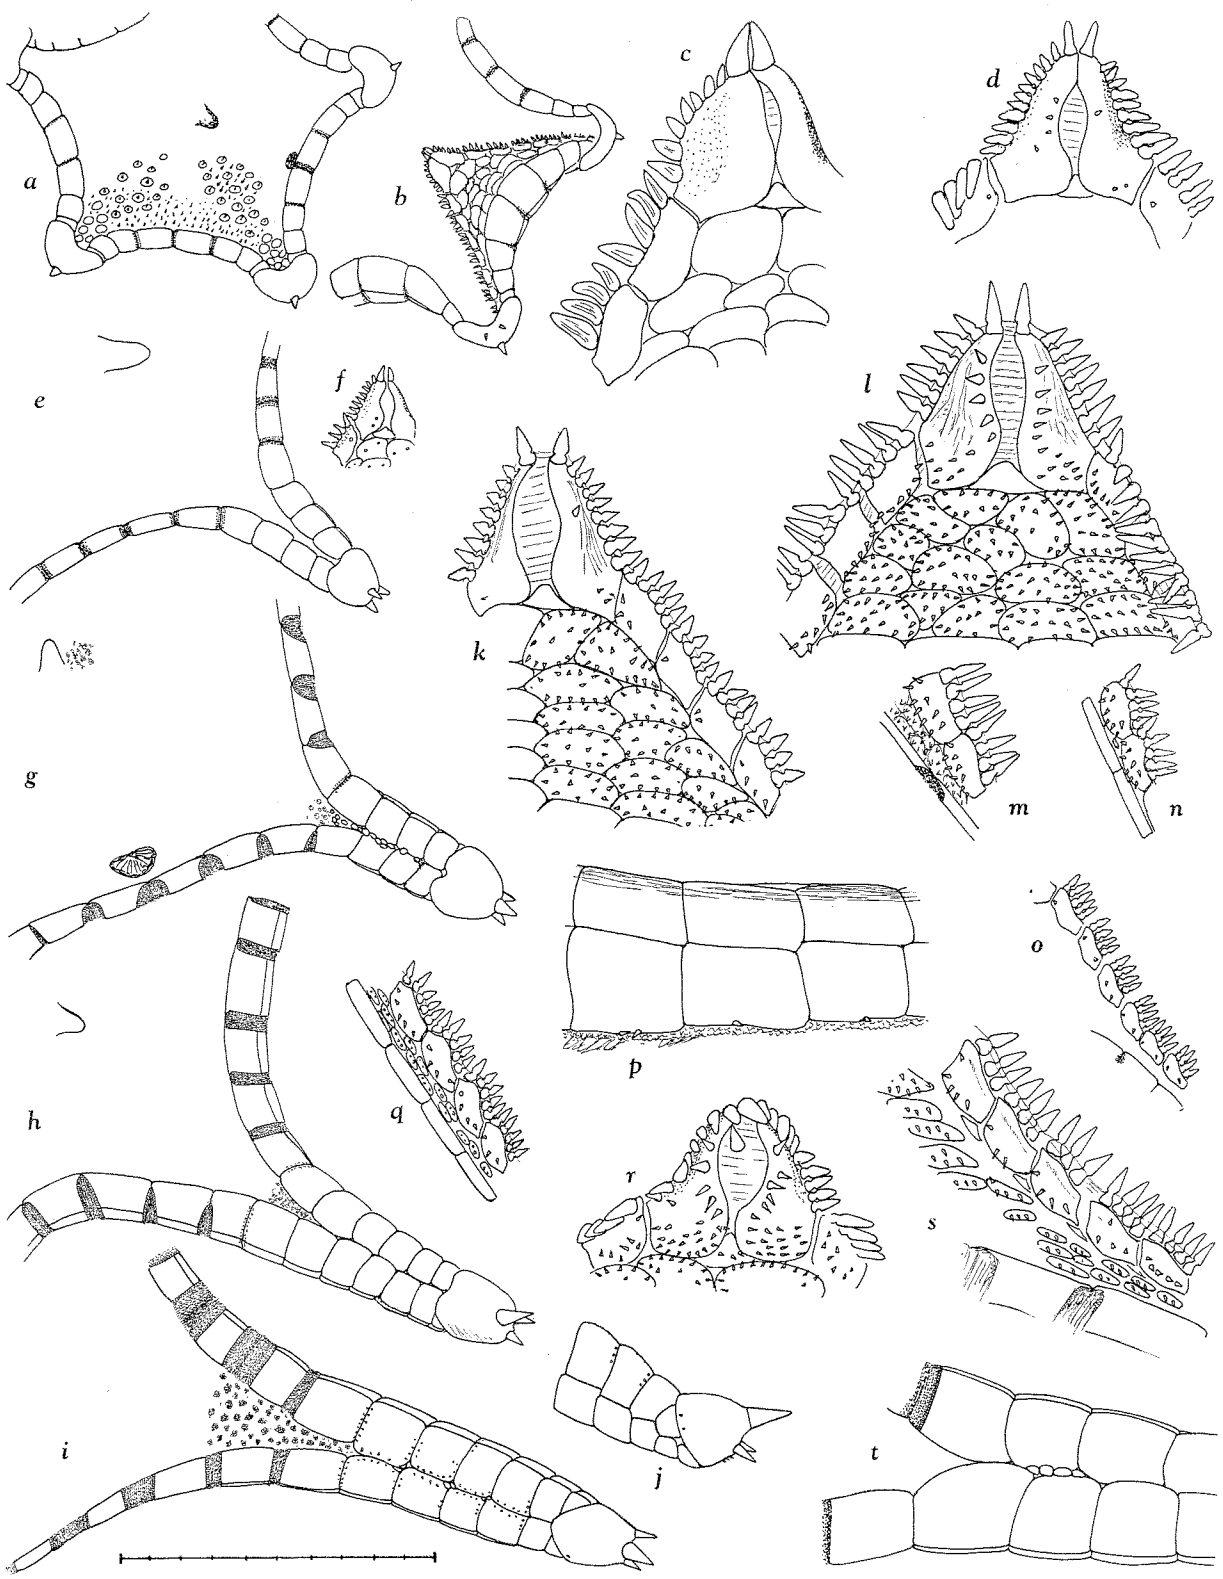

Fig. 6. *Hyphalaster inermis*. a-c) St. 24, R/r 6/4 mm; a, dorsal view; b, ventral view; c, jaw in four times larger scale. d) St. 30, R/r 14/7 mm, jaw (in twice the usual scale). e-f) St. 24, R/r 12/6 mm, part of dorsal side and jaw. g) St. 280, R/r 16/8 mm, (see also fig. 7o). h) St. 192, R/r 17/6 mm. i-j) St. 282, R/r ab. 20/11.5 mm, same arm in dorsal view and from the side, (see also fig. 7f). k) St. 282, R/r 48/15 mm, part of ventral side. l-n) St. 238, R/r ab. 53/21 mm; l, part of ventral side; m, adambulacralia nos. 8-9; n, adambulacralia nos. 17-18, inferomarginalia nos. 10-11, (see also fig. 7g,h,p). o) St. 99, R/r 18/9 mm, adambulacralia nos. 1-6. p) St. 234, R/r 75/21 mm, marginals nos. 10-12 in side view. q) St. 238, R/r 46/16 mm, adambulacralia nos. 15-18. r) St. 99, R/r 57/18 mm, jaw, (see also fig. 7q). s) St. 238, R/r ab. 44/19 mm, part of ventral side with the adambulacralia nos. 4-8. t) St. 30, R/r 49/21 mm, basal part of arm in dorsal view.

Scale: 10 mm (in d 5 mm, in c 2.5 mm).

st. 99, and 7, the outermost ones rudimentary though, in that from st. 30. In all larger specimens there are in each interradius from 7 to 11 cribriform organs. The number is often somewhat varying in the different interradii of the same specimen, and may be unequal to each side of the median organ (thus there may be 8 or 10 cribriform organs in the interbrachial series).

The cribriform organs are generally developed from the dorsal side, and the rudimentary ones therefore yet solely occupy the superomarginal sutures. Full-grown specimens have at least 7 cribriform organs; and 7 cribriform organs only are also found in some of the largest specimens, with R up to 58 mm, while 11 cribriform organs are found in some interradii of a specimen from st. 52 with R 50 mm, in all interradii of the specimen from st. 65 with R 48 mm, and in about two-thirds of the specimens from st. 30. In this latter population even a specimen so small as with R/r 14/7 mm shows in some interradii 11 cribriform organs (the outer ones, however, still rudimentary). One specimen with R/r 49/9 mm also shows a twelwth, rudimentary cribriform organ in one interradius. The remaining specimens from st. 30 all have 9 cribriform organs in each interradius. The large number of cribriform organs in the population from st. 30 is connected with a tendency of the superomarginal plates to remain separate for a longer distance than is usual in the other specimens at hand (the disk thus being relatively larger).

The large cribriform organs are in general composed of up to 16 rows of papillae. In the specimens from st. 30 there may be even 22 rows of papillae, and in these specimens successive cribriform organs are often in contact. The structure of the cribriform organ is papilliform, with the calcareous papillae slender and flattened. Those of the outer covering series are not much larger than the other ones. The series of covering papillae extend in a continuous series from one dorsal corner of the organ to the other dorsal corner, so that the cribriform organs typically are well marked off ventrally. In large specimens, however, the median cribriform organ, which becomes gradually larger with age, may appear indistinctly marked off also ventrally, where it adjoins the spinulated ventral disk area.

The terminal ossicle is rather conspicuous in the juvenile specimens, broad, and with the adoral dorsal margin concave, in connection with the dorsal integument here reaching to it between the opposite superomarginals (fig. 6*a*). It carries 3 spines, a distal terminal one and a pair of subterminal ones, which latter apparently are not yet developed on some of the terminal ossicles of the smallest specimen at hand, with R 6 mm. In the somewhat larger specimens (in which the distal superomarginals encase the arms) the terminal ossicles become more elongate, oval in outline, when seen from above, and placed slightly dorsal to the end of the arms, covering one or usually two rudimentary superomarginals. In medium-sized specimens the terminal ossicles are still rather prominent, but in the largest specimens they become fairly inconspicuous, being here flush with the superomarginals of the arm end. As a rule the terminal ossicles, also in the largest specimens, bear only 3 fairly short and conical spines (the unpaired terminal one and the pair of subterminal ones), but large specimens exceptionally may have two pairs of subterminal spines.

The whole dorsal side of the disk is armed with a close pavement of fairly uniform small paxillae with rather granular spinelets. (Fig. 7*n, q-s, u-v*). Embryonic plates are still discernible radially in the juvenile specimens with R about 6-7 mm (fig. 6*a*), but are in the state of being absorbed, and with paxillar shafts developing centrally upon them. And the paxillae covering the central and interradial areas are yet with only single spinelets. In the juvenile specimen with R/r 10/5 mm the paxillae carry 1, 2, or 3 spinelets.

The average number of spinelets on the paxillae, as well as the largest number found, varies considerably in the different specimens. In specimens with R about 20 mm, the largest number of paxillar spinelets ranges from 6 to 12 in different individuals; in specimens with R about 30 mm it ranges from 15 to 18, in those with R about 40 mm from about 15 to about 20. In the larger specimens the maximal number of spinelets on the paxillae varies generally from about 15 to about 20, and is exceptionally about 30. In the two large specimens from st. 24, with R 62 and 64 mm, the average number of spinelets on the paxillae is about 12 and 16 respectively, with 2-4 central spinelets surrounded by a circle of peripheral ones; and the largest number of spinelets counted is 18 and about 25 respectively. Incidentally, these two large specimens from st. 24 correspond closely in size and in number of superomarginals (18-19) to those described by KOEHLER (1907) under the name of *H. fortis,* the paxillae of which, however, were stated to have about 10 central granules surrounded by a circle of peripheral

ones. Such large paxillae with e.g. 13 central spinelets surrounded by a circle of 17 peripheral ones, are in the present material only observed in a specimen from st. 99 with R/r 58/21 mm and 17 superomarginals. The paxillae are all more or less circular (to polygonal) in contour. They are all about subequal in height, the larger ones being about as wide as high, and the smaller ones correspondingly more slender. The paxillar shafts show a distinct constriction which marks off the basal part, imbedded in the integument. (Fig. 7*r*).

Papulae have been observed in some specimens (fig. 7*s*), also fairly close to the center of the disk.

An apical appendage, or at least an apical cone, is usually distinct in the small specimens. An apical appendage may be present also in medium-sized specimens, and an apical cone may be found in specimens as large as with R up to 64 mm. Several large specimens, and also a few smaller ones, however, do not show any apical prominence at all. They usually have the central area provided with paxillae of a distinctly smaller size than those of the main part of the disk, but even such a difference in the armature of paxillae is not always present.

The madreporite is roundish or more or less distinctly tangentially elongate, perhaps kidney-shaped with the concave side adcentrally directed. In grown-up specimens its diameter is slightly less than the length of the adjoining marginals, but in the juveniles it is relatively smaller. It may lie close to the marginal plates, but usually it is separated from these by one or three (4) rows of paxillae. Its striae radiate from a point situated eccentrically near the adcentral margin.

The adambulacral ossicles of the disk are rather subrhomboid in contour, whereas those in the free arms are rather subcrescentic. Each ossicle bears along the furrow a series of 4-5 subequal and uniformly spaced spines (exceptionally, on some of the proximal ossicles in a large specimen, there are 6 furrow spines). The furrow spines are rather spearhead-shaped (lanceolate), with a constriction in their lower part, marking the extension of the connecting web, and their outer part more or less distinctly flattened in vertical direction, subquadrangular or subtriangular in cross-section, and with a blunt end. On the surface of the adambulacral ossicles there are a few subambulacral spinelets, in small specimens e.g. often a minute one on the adoral part of the ossicle, and a slightly larger one aborally, while in large specimens there may be up to 5 subambulacral spinelets in a longitudinal series, and on the most proximal plates in addition a few more spinelets between this series and the furrow edge, especially on the adoral part of the ossicle.

The number of adambulacral ossicles is e.g. 7-8 in a specimen with R 6 mm and 3-4 superomarginals, 13 in one with R 10 mm and 6-7 superomarginals, 17 in one with R 18 mm and 9 superomarginals, 27 in one with R 48 mm and 17 superomarginals, and 27 too in one with R 57 mm and also 17 superomarginals.

The oral ossicles (fig. 6*c, d, r*) bear along their margin a series of on an average 8 oral spines, the number usually varying from 7 to 9, occasionally being 10, and exceptionally 11-12. A specimen with R/r only 14/7 mm thus has 12 oral spines on one of the oralia, whereas the others bear 9-10 such spines. The oral spines are shaped like the adambulacral ones.

The surface of the oral ossicles is naked in the juvenile specimens at hand, but in the larger specimens there is always a varying number of suboral spinelets and spines. A specimen with R 10 mm thus is provided with a couple of suboral spinelets; and medium-sized specimens usually have a few conical spines on the protruding part along the suture and a varying number of spinelets on the distal surface. In the large specimens there may be up to 6 small conical suboral spines in a series along the suture, and up to 10 suboral spinelets distally.

The primary oral ossicle is well exposed, showing a triangular surface, and is often provided with a few spinelets.

The ventrolateral area is armed with a pavement of plates, which slightly overlap in adoral direction. In the juvenile specimens these plates are arranged in about 4 tangential rows, in the medium-sized specimens in about 10, and in the largest specimens in up to 12-13 of such rows. Twelve is the usual maximum of tangential rows of ventrolateral plates, and the number may vary in different interradii. The ventrolateral plates are further arranged in radiating series, two and two corresponding with one adjoining marginal plate. The proximal and largest ventrolateral plates are irregularly shaped, whereas the more distal ones are transversely elongate or subhexagonal. Minute ventrolateral plates extend somewhat along the free arms, e.g. about half their length in a specimen with R 48 mm and 17 superomarginal plates. The ventrolateral plates are still naked in the juvenile specimens with R less than 10 mm, but otherwise they bear a fairly uni-

formly spaced armature of spinelets, on the proximal larger plates generally placed along the adoral border (e. g. in a number of about a dozen, or a little more, to a plate) on the more distal plates arranged in one or two median series, parallel to the long sides.

Some specimens are seen covered with a thick, deciduous skin.

The Indian Ocean specimens. (Figs. 6*g-n, p-q, s;* 7*a-m, o-p, w-æ.* Pls. II-III):

The Galathea Expedition collected a total of 62 specimens of *Hyphalaster inermis* in the Indian Ocean, viz. 14 specimens in three dredgings near Durban (sts. 186, 192, 193), 13 specimens in two dredgings near Mombasa (sts. 234, 238), and 35 specimens in three dredgings near Ceylon (sts. 280, 281, 282). As was to be expected, this additional large material somewhat enlarges the infraspecific variation known.

The single specimen from st. 186 has R/r 33/14 mm, and that from st. 192 R/r 17/6 mm. The twelve specimens from st. 193 have R/r respectively 18/8, 24/10, 26/10, ?/11, 31/12, 32/12, 32/13, 33/12, 33/12, 34/13, 34/14, and 36/12 mm. The single specimen from st. 234 has R/r 75/21 mm, and the twelve specimens from st. 238 have R/r 39/15, 44/19, ?/19, 46/16, 53/20, 53/21, 58/20, 60/18, 62/20, 65/21, 70/20, and 70/22 mm. The two specimens from st. 280 have R/r 16/8 and 59/18 mm, that from st. 281 has R/r 45/14 mm, and the thirty-two from st. 282 have R/r 20/11, 33/13, 36/14, 38/13, 43/14, 48/15, ?/17, 56/19, 58/18, 62/18, 62/21, 62/22, 63/20, 64/20, 65/18, 67/20, 67/20, 67/21, 68/22, 68/22, 69/22, 70/21, 70/21, 70/21, 70/25, 72/24, 74/19, 74/20, 74/23, 75/23, 75/24, and 80/24 mm.

Several of these specimens from the Indian Ocean are thus distinctly larger than anyone known from the Atlantic. The ratio R/r varies from about 2 in the smallest specimen at hand up to about 3 in specimens with R about 60 mm (which corresponds to the largest Atlantic specimens hitherto known) and increases (in conformity with the positive allometric growth of the arms) to about 3.5 in specimens with R about 70-80 mm or more, exceptionally to almost 4, as in a specimen with R/r 74/19 mm.

The numbers of superomarginal plates and cribriform organs are as follows:

R	Number of supermarginals	Number of cribriform organs
16 mm	7-8	(5)-7
17-18 mm	9	(5)-7
20-34 mm	10	7-9
20-33 mm	11	7-9
26-34 mm	12	7-9
32-39 mm	13	7-11
36-39 mm	14	7-11
36-58 mm	15	9-11
43-67 mm	16	9-11
58-70 mm	17	9-11(-13)
59-72 mm	18	9-11
59-75 mm	19	9-11(-19)
62-80 mm	20	9-13
62-75 mm	21(-22)	11-15

Eleven cribriform organs in each interradius is the usual maximum, but 13 to an interradius occur in three specimens with R 58, 62, and 70 mm, and 17, 20-22, and 17-21 superomarginals respectively. Fifteen cribriform organs are found in the interradii of a specimen with R/r 74/19 mm and 21 superomarginals. The extraordinarily large number of 17-19 cribriform organs to an interradius is found in a specimen with R/r 67/20 mm and 19 superomarginals (pl. III 1). The largest number of superomarginals, 22, is found in a specimen with R/r 62/18 mm.

The superomarginals in general join their opposites in the midline of the arms from the fifth or sixth pair, or, more rarely, from the seventh pair. In the present material the joining of the superomarginals may, however, take place both more proximally as well as more distally. In a specimen from st. 193 with R/r 31/12 mm the fourth superomarginal plates thus meet their opposites for a distance of their length in all five arms, and in another specimen from the same haul, R/r 26/10 mm, they do so in some of the arms. In the available twelve specimens from this population from st. 193, the disk is upon the whole relatively small, the superomarginals as a rule meeting their opposites from no. 5. In the population from st. 282, represented by 32 specimens most of which are large ones, the disk area on the other hand is in general relatively large; the opposite superomarginals here usually join from the sixth or seventh plates, and in a few specimens, with R/r 64/20, 67/20, 70/21, and 74/19 mm, they at least in some arms do not join until plates no. 8. In the specimen with R/r 67/20 mm (pl. III 1) the seventh pair of opposite superomarginals are separated in all the arms by 2-3 rows of paxillae, and in one arm a single row of paxillae also separates the eighth pair of superomarginals in their whole

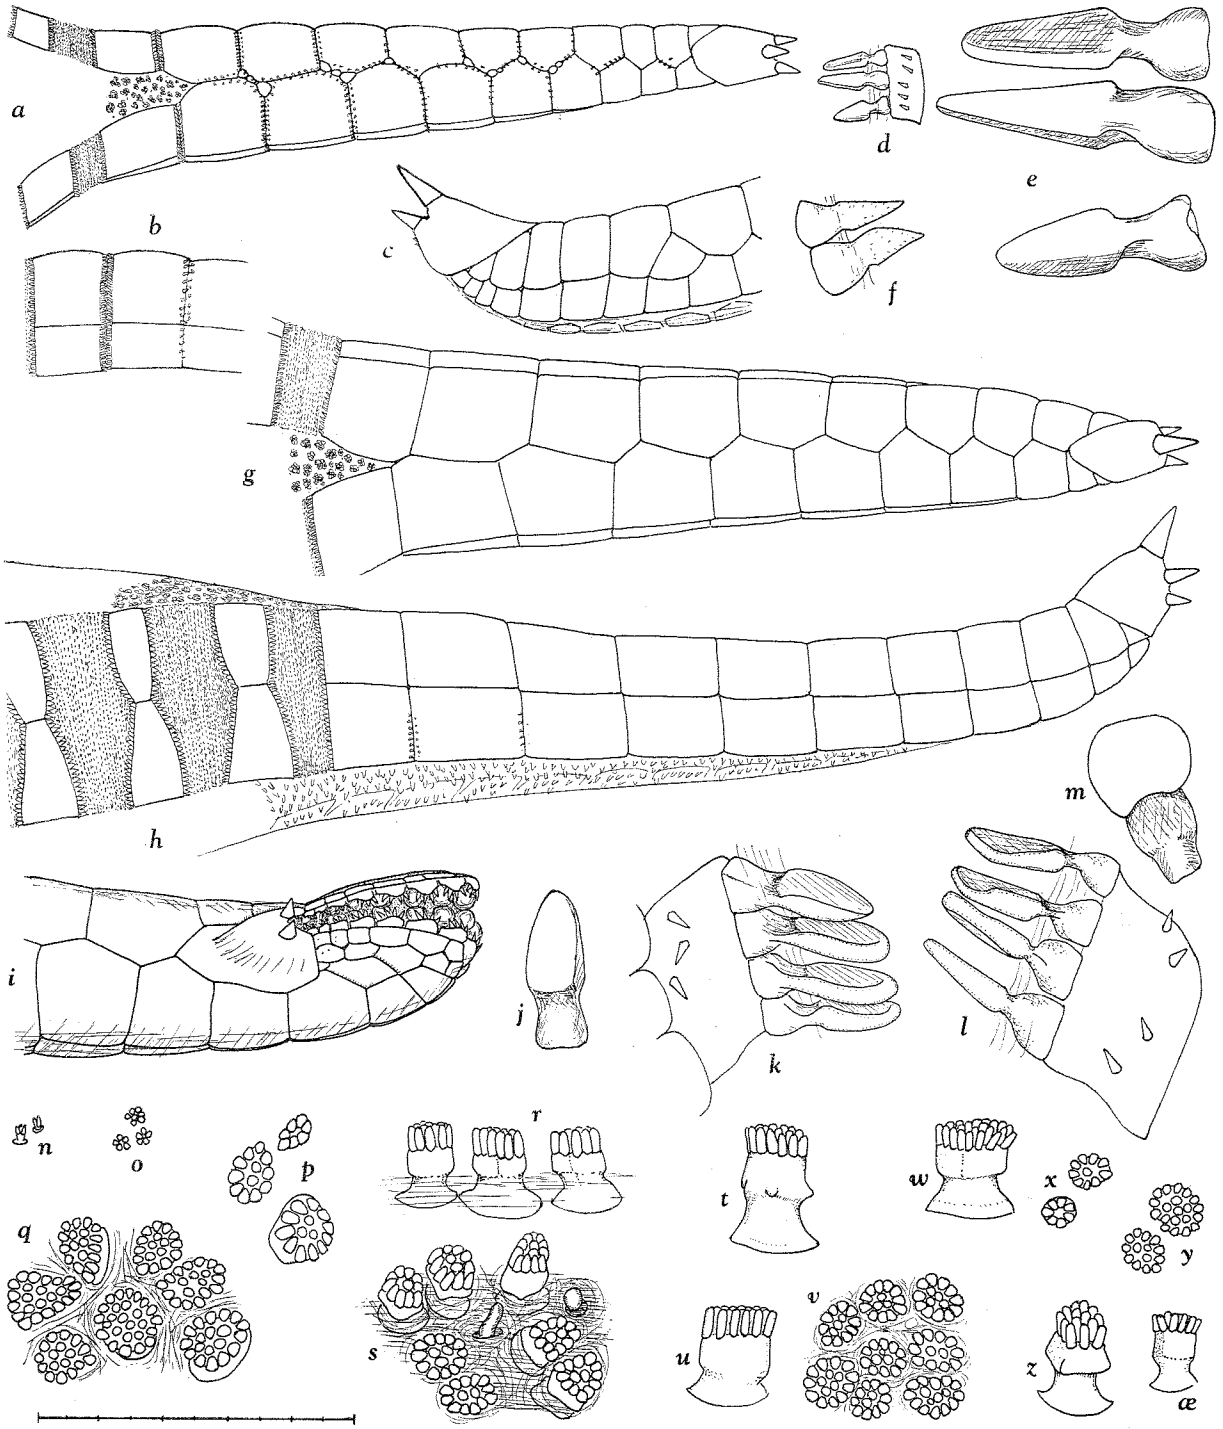

Fig. 7. *Hyphalaster inermis*. a-b) St. 282, R/r 43/14 mm; a, arm in dorsal view, first joining superomarginals are nos. 6; b, marginals nos. 5-7 in lateral view. c) St. 282, R/r 62/18 mm, (see also w-æ). d-e) St. 282, R/r 74/19 mm; d, adambulacral ossicle no. 6; e, same spines in four times larger scale. f) St. 282, R/r about 20/11 mm, oral spines, (see also fig. 6 i-j). g-h) St. 238, R/r about 53/21 mm, arm in dorsal view and in lateral view, (see also p and fig. 6 l-n). i) St. 282, R/r 67/20 mm, abnormal arm end. j-k) St. 193, R/r 36/12 mm; j, furrow spine seen from the adoral side; k, adambulacral ossicle no. 4. l-m) St. 193, R/r ?/11 mm; l, adambulacral ossicle no. 4; m, furrow spine from the adambulacral ossicle no. 1 seen from the adoral side. n-æ) Dorsal paxillae; n, st. 24, R/r 12/6 mm; o, st. 280, R/r 16/8 mm; p, st. 238, R/r ab. 53/21 mm; q, st. 99, R/r 57/18 mm; r-s, st. 24, R/r 64/21 mm; r, three paxillae in side view; s, a group of paxillae in dorsal view and with a few papulae observable; t, st. 282, R/r 64/20 mm; u-v, st. 24, R/r 64/21 mm; w-æ, st. 282, R/r 62/18 mm.
Scale: 10 mm in a-d and g-i, 2.5 mm in e-f and j-æ.

length (this specimen with the unusually large disk area is also the one with the exceptionally large number of up to 17-19 cribriform organs in each interradius). In the population from st. 282, however, also a specimen as large as with R/r 74/20 mm (pl. III 2) may be found with the opposite superomarginals no. 5 meeting, at least in part.

The superomarginals as usual often subalternate to a varying degree, also in different arms of the same specimen. The regular quadrangular appearance of the plates may be completely lost in some arms, in which especially the superomarginal series may be broken up into triangular or irregularly polygonal plates. The superomarginals sometimes appear very slightly tumid, which may give the arm a somewhat annulated appearance (fig. 6*g-h*) as was described by SLADEN (1883 p. 240) for the type-specimen of *H. inermis*. The Indian Ocean material likewise includes some specimens in which a varying number of small rounded supplementary plates are inserted between the otherwise joining superomarginals (fig. 7*a*), generally only in the proximal part of the arms, but occasionally almost to the terminal ossicle. In one specimen from st. 282, R/r 74/23 mm, such plates occur in an almost continuous row for a distance of six succeeding superomarginals. About one-fifth of the specimens from st. 282 have secondary dorsal arm plates.

In the smallest specimen in this material, one from st. 280 with R/r 16/18 mm (fig. 6*g*), the fourth and fifth pairs of superomarginals are separated by a series of small rounded plates, in appearance similar to the secondary dorsal arm plates of the large specimens, but in the present case probably to be interpreted as embryonic plates which have not yet been replaced by the paxillae of the full-grown individual. Nor are the paxillae of the arm bases in this specimen fully developed, having only a few spinelets on the paxillar shafts which are formed on the not yet completely absorbed embryonic plates.

In the specimens with R less than about 35 mm, the arm plates are generally naked, whereas in the larger specimens they often bear some minute granules or granuliform spinelets, as was also the case in a few of the largest specimens from the tropical East Atlantic, described above, and in some of the Greenland specimens described by LIEBERKIND (1935). The marginal granuliform spinelets appear to be so easily lost that a description of their distribution may often be very uncertain. Where best developed, this armature of spinelets is found as a single series all way round along the margins of the arm plates, and thus at the vertical sutures gives the impression of a rudimentary cribriform organ with yet only two series of papillae. The marginal spinelets, however, are in general confined to the more proximal arm plates, though in some specimens they may occur to the arm end. In many specimens they are developed only along the aboral vertical margins (of the inferomarginal as well as of the superomarginal plates). In others they are developed also along the adoral vertical margins (here always being of a smaller size) and along the ventral margin of the superomarginals. Only more rarely do they occur also along the dorsal margin of the inferomarginals, and only rather exceptionally do they form the continuous series all around along the margins of both superomarginal and inferomarginal plates.

Some of the inferomarginals of the arms in the single specimen from st. 234, R/r 75/21 mm, bear medially near the ventral margin one or a few spinelets (or minute spines), slightly larger than the neighbouring ventrolateral spinelets (fig. 6*p*). It is probably a character attained with age, but is not seen in any of the other specimens at hand.

The arms of the larger specimens of *Hyphalaster* apparently are frequently subject to damage in the living animal, since in the present material several specimens are observed with arms in different stages of regeneration. One specimen from st. 282, with R/r 56/19 mm and 16 superomarginals, has once lost an entire arm, and the wound has then healed by the marginal plates closing over it, so that the specimen now appears with an almost regularly quadrate disk with an arm extending from each corner (pl. XIII 4). Probably also the peculiar abnormality to be described on p. 69, of the arm ends being bent back and fused with the more proximal part, is to be assigned to a regeneration after an injury. The specimen from st. 234 with R/r 75/21 mm has the single preserved arm furnished with two terminal ossicles, one above the other, and also this may be due to an irregular regeneration.

The number of cribriform organs by different lengths of R has been recorded above. The largest of the specimens at hand, R/r 80/24 mm, has 13 cribriform organs in some interradii, and 12 in the others. The specimen with R/r 67/20 mm and 19 superomarginals, which meet from pairs no. 8 (pl. III 1) has in each interradius 13-15 fully developed cribriform organs, reaching from the dorsal to the ventral side of the disk, and to each side of this series two additional, rudimentary ones. The spec-

imen thus shows the unusual feature of having cribriform organs formed also around the vertical suture of a set of marginal plates belonging to the arm. The rudimentary organs are best developed at the horizontal suture, the proximal one reaching to the ventral but not to the dorsal side of the disk, and the distal one, with up to 6 rows of papillae, reaching only to about the middle of either series of marginals.

The largest cribriform organs comprise up to about 24 series of papillae, and in some specimens the median ones merge in part with their neighbours at the dorsal edge of the marginals and possibly also at the horizontal suture. In a specimen with R/r 70/21 mm and 13-14 cribriform organs, the 9-11 median ones thus are in contact medially, at the horizontal marginal suture, and dorsally close to the disk, thus leaving free only a triangular patch on the lower part of the inferomarginals, and a diamond-shaped patch on the median part of the superomarginals. Usually, however, the cribriform organs are well separated.

The terminal ossicles carry also in the large specimens of the present material typically 3 fairly short spines. (In some of the larger specimens it looks as if the terminal spines have been worn down in the living animal, which cannot be stated with certainty, however, since these spines are so easily lost, and thus may have been lost during dredging or later during the handling of the specimens). Sometimes, but rarely, there are two pairs of subterminal spines, thus 5 terminal spines in all. The terminal ossicle may be rather conspicuous also in some of the largest specimens at hand.

One specimen from st. 282, R/r 67/20 mm, shows a peculiar abnormality in two of the four arms preserved. The distal arm end is bent up and backwards for a length of about 1 cm and coalesced with the dorsal side of the arm (fig. 7*i*, pl. XIII 3), the outermost part of the ambulacral furrow thus being dorsal to the arm end, and the terminal ossicle becoming pushed in between the opposite superomarginals as a triangular "plate", its adoral end (the distal end of the normal ossicle) being low and flush with the superomarginals, while the aboral end is elevated and bears a pair of spines (the subterminal ones, whereas no trace is found of the distal terminal spine).

The largest paxillae bear in the specimens with R up to about 40 mm, from 10 to about 15 (exceptionally 20) spinelets. In specimens with R 60 mm or more, the largest paxillae carry from about 10-12 to 20-25 spinelets (fig. 7*p, w-æ*), sometimes, as in the specimen with R 80 mm, even up to about 30 spinelets. The specimen from st. 234, with R/r 75/21 mm, e.g. has the paxillae provided with from about 6 to 12 spinelets, in the small paxillae in a circular crown, in the large ones with a central spinelet surrounded by a circle of peripheral ones.

Papulae are as usual in the porcellanasterids rarely observable. In the specimens in which they are seen they are present in a slightly larger number than the paxillae, each paxillae e.g. being surrounded by 5-6 papulae, and each papula being found in the space between three adjoining paxillae.

A short apical appendage is present in some of the small specimens, and in the others there is an apical cone. An apical cone is often present in the large specimens too, thus also – though a very low one – in the largest specimen, with R 80 mm. Otherwise there is in the large specimens merely a small central area with smaller paxillae.

The madreporite shows no deviations from the appearances found in the Atlantic material described.

The adambulacral armature (fig. 6*k-n, q, s*) is as a rule as described for the Atlantic material, with 4-5 subequal lanceolate furrow spines, and some spinelets in an irregular row along the interradial margin of the adambulacral ossicles; but the number of furrow spines may vary from 3 to 6, and there may be only a single (or perhaps none) subambulacral spinelet. A few specimens with R ranging from 39 to 74 mm thus have only 3 furrow spines on some or on most of the adambulacral ossicles of the disk area, whereas the adambulacral ossicles in the arms usually have 4-5 furrow spines. As a general rule the adambulacral ossicles of the free arms have either the same number of furrow spines as those of the disk, or one more, and the few ossicles found with 6 furrow spines therefore always belonged to the free arms of fairly large specimens, R 58-74 mm.

The furrow spines are generally spearhead-shaped (fig. 7*e*) with a conical basal part, a constriction to where the web connecting them reaches, and a longer obtusely pointed distal part which is flattened in a direction vertical to the furrow (in cross-section being subrectangular, subtriangular, or subcrescentic). In about one-third of the specimens from st. 193 (R 30-36 mm) however, all the furrow spines, and also the oral spines, have the distal part much broader, thus assuming the appearance of a handmirror (fig. 7*l-m;* pl. III 4). The ventral appear-

ance of these specimens becomes very characteristic through this feature, but it is evident that it is only an individual variation, since the other specimens of the same population are provided with furrow spines of the usual spear-head shape (fig. 7*j-k;* pl. III 3) or, in one case, of an intermediate shape.

The subambulacral armature is best developed on the ossicles of the proximal part of the free arms, on which there may be about ten spinelets arranged in two irregular longitudinal series. In small specimens, the adambulacral ossicles of the disk area may sometimes have yet only a single, always adorally placed spinelet developed on their surface, so also a specimen with R 48 mm from st. 282 (in which some ossicles even appear completely naked); and specimens as large as R 70 mm may have only a couple of subambulacral spinelets. In the young specimens the subambulacral spinelets may appear relatively larger than in the older ones.

The number of adambulacral ossicles in relation to the size of the specimens and the number of superomarginal plates appears from the following examples:

R	Number of superomarginalia	Number of adambulacralia
16 mm	7-8	13
17 mm	9	17
20 mm	10-11	17
33 mm	12	21
38-46 mm	14-16	24-26
48 mm	16-17	27-29
53-60 mm	14-19	27-32
62 mm	20	33-34
64-70 mm	17-21	32-35
74 mm	19-21	36-38
80 mm	20	34

In fairly expanded specimens the end of the ambulacral ossicles may be seen between the adambulacral ones also in the proximal part of the arms.

The oral ossicles (fig. 6*k-l*) generally carry 7 or 8 marginal spines, of which the proximal one is about twice as large as the others. Exceptionally some oralia bear only 6 marginal spines, and other oralia may be found with 9 or even 10 marginal spines. Ten marginal oral spines are thus found in the large specimen with R 80 mm (the number of oral spines here varying from 8 to 10) as well as in a specimen with R only 17 mm.

The suboral armature consists of a varying number (up to about half a dozen) of short conical spines along the sutural margin, and further of a varying number of spinelets on the distal part of the ossicle. In the small specimens there may still be only a few spinelets. In the large specimens a suboral armature is usually well developed; and the proximal of the spines at the sutural margin may attain a length subequal to that of the large proximal oral spine, so that the pair of oralia forming a jaw, seems to be provided with a small cluster of mouth-spines. (Sometimes the suboral spines are found not on the oral ossicles proper, but on the skin extending over the suture. This must be due to an abnormal turning of the oralia in the preserved specimens and a contraction of the integument).

The marginal oral spines are – like the adambulacral ones – typically spearhead-shaped, as was also the case in the Atlantic material. In 3 of the 12 specimens from st. 193 they are, however, (like the adambulacral spines here) much broader, hand-mirror- or shovel-shaped, whereas they are of an intermediate appearance in a fourth specimen.

The primary oral ossicle may occasionally be armed with a few spinelets, as was also to be observed in some Atlantic specimens. One specimen from st. 282, with R about 68 mm, has all the primary oral ossicles provided with a number of spinelets similar to those occurring on the ventrolateral plates. Another specimen from the same population, with R/r 70/21 mm, has minute spinules on one of these ossicles, whereas the four others are bare.

The ventrolateral plates are in the present large specimens arranged in from 12 to 14, exceptionally up to 16 tangential rows, and 14 such rows are e. g. also found in a specimen with R only 58 mm. Small ventrolateral plates often extend in a narrow strip almost to the end of the arms. When the integument is preserved, the ventral area with the rather uniform covering of spinelets has a velvet-like appearance. Fairly distinct radiating spineless ridges often extend between the double radial rows of ventrolateral plates, from the adambulacralia to the marginal sutures.

Notes on the Pacific specimens:

The Galathea Expedition also collected a few specimens of *Hyphalaster inermis* in two dredgings in the Kermadec Trench north of New Zealand (sts. 664 and 668).

The two specimens from st. 664 have R/r 62/20 and about 23/9 mm respectively, (the latter specimen is very damaged). The one from st. 668 has R/r 13/5 mm.

The specimen with R/r 62/20 mm has 21 superomarginals, which join from nos. 7(-8), and 12-13 cribriform organs of which some may coalesce at

the horizontal suture. That with R/r about 23/9 mm has 13-14 superomarginals (a rather high number), which join from nos. 6(-7), and 9-11 cribriform organs. The other with R/r 13/5 mm has 8 superomarginals which join from no. 5, and 9 (+ 2 rudimentary) cribriform organs. The marginals of the arms are naked in all the specimens. The terminal ossicles bear 3 spines.

The paxillae carry 9-18 spinelets in the large specimen, up to 8 spinelets in the medium-sized one, and 2-5 spinelets in the small one. The madreporite in the large specimen e.g., is transversely oval with the furrows radiating from an adcentral point. There is a short apical appendage in the small specimen, and a distinct apical cone in the medium-sized one.

The ambulacral armature consists proximally in the large specimen of 4 furrow spines and about 3 subambulacral spinelets, and in the arms of 4-5 furrow spines and 4-5 subambulacral spinelets. The same applies to the medium-sized specimen. In the small specimen there are 3(-4) furrow spines and a couple of subambulacral spinelets, which here appear relatively larger than in the other specimens. The number of adambulacral ossicles in the specimens is 32, 21, and 12 respectively.

The oral armature consists in the large specimen of 7 marginal spines and about 3 suboral ones along the suture, besides up to 5 spinelets on the distal surface. The medium-sized specimen has 7 marginal spines (on one ossicle 8), and 2 suboral ones at the suture and about 4 suboral spinelets distally. The small specimen has 7-8 marginal spines, and suborally 2 small spines at the suture and a single spinelet distally.

The ventrolateral plates are arranged in 14-15, 10-11, and 5 tangential rows respectively. In the two larger specimens they carry 5-9, in the small one up to 5 granuliform spinelets. In the large specimen the ventrolateral plates extend almost to the end of the arms, to the inferomarginals no. 18.

Biological remarks:

The stomach content of these specimens of *Hyphalaster* is the usual mud, presumably rich in bacteria, and with foraminiferans and various other organic items. A small twig, 23 mm long and 1 mm thick, was e.g. removed from the stomach of a specimen from st. 282 with R abot 65 mm.

A few eggs, 0.5-0.6 mm large, were found in the otherwise almost emptied gonads of a fairly large specimen from st. 238.

Ascothoracids were found in two specimens from st. 282 and in one from st. 52. Another specimen, from st. 30, shows a large calcified tumor ventrally, which probably also indicates the presence of an ascothoracid parasite. Larvae in the cypris-stage were found attached to the dorsal side of one of the specimens from st. 282.

Myzostoma specimens were found on three medium-sized specimens from st. 52, and on a large one from st. 282. They were found attached to the dorsal side, to the marginal plates, as well as to the ventral side.

Discussion:

All the 109 specimens of *Hyphalaster* s.str. collected by the Galathea Expedition in a total of 15 different dredgings, scattered over the tropical eastern Atlantic, the Indian Ocean, and the south-eastern Pacific, shall have to be grouped in a single species, as is evident from the descriptions given above. The study of the present material has confirmed that LIEBERKIND was right in considering all the hitherto recorded Atlantic specimens of *Hyphalaster* as of one species only (*H.parfaiti* Perrier, 1885), but it has further led to the conclusion that this species is the same as the *H.inermis* described by SLADEN in 1883 on specimens from off Japan.

SLADEN states in the original description of *H.inermis* that "The adambulacral plates join up to the infero-marginal plates along the whole length of the free portion of the ray, and there is consequently no extension of the interbrachial area along the ray". As described above, ventrolateral plates have been found extending a varying distance down the free arms of the examined larger specimens, but the feature is in part one of age, and smaller specimens of e.g. the same size as the type-specimen, R about 20 mm, may have the ventrolateral plates restricted to the actual disk area. SLADEN mentions that "A slight elevation of the surface is present in the median radial line, opposite the base of each ray, and about a third of the distance from the margin to the centre". These radial elevations are very distinctly shown in the published figures, and the present author has not seen any specimens which really do show a similar dorsal aspect. But this appearance cannot be considered of any taxonomical importance; probably the type-specimen of *H.inermis* is with an empty stomach, and with the disk area contracted to such a degree that the skeleton around the closed ambulacral furrows has caused the said dorsal radial elevations.

Distribution:

Hyphalaster inermis is recorded from twenty dredgings in the northern and the tropical part of the Atlantic, from eight dredgings in the Indian Ocean, and from four dredgings in the Pacific. (Fig. 31). It is noteworthy, however, that it has not been taken in any of the rather numerous abyssal dredgings in the eastern Pacific along the American coasts. Its known bathymetrical range is from 2278 to 5413 m (7 finds in less than 3000 m, 11 between 3000 and 4000 m, 9 between 4000 and 5000 m, and 5 in more than 5000 m). It has been found on bottoms of mud, globigerina ooze, and calcareous clay, and at temperatures ranging from 1.1°C. to 3.9°C.

Hyphalaster giganteus Macan, 1938

MACAN 1938 pp. 331-333, pl. $1_{3,7}$.

The description of this species is based on a single specimen dredged by the John Murray Expedition in the Arabian Sea near the Carlsberg ridge (st. 171: about 9°08'N, 53°30'E, 3840-3872 m). It has R/r 82/24 mm; 26 superomarginals, the distal 21 in contact with their opposites; 9 cribriform organs; disk with uniform paxillae with a whorl of 7-9 spinelets surrounding 1-2 central ones. No apical cone. Adambulacralia with 4-5 conical furrow spines and two subambulacral spinelets. Oralia with 7-8 marginal spines and 5 suboral granules. The ventrolateral plates devoid of granules or spines.

MACAN notes that the adambulacral ossicles are mostly badly damaged. It may be inferred, therefore, that the whole ventral side of the specimen is poorly preserved, and that the description of the ventrolateral area as being without spines, perhaps may not have applied to the intact individual. If this is the case, *H. giganteus* is only a large specimen of the species *H. inermis* with which, as also noted by MACAN, it otherwise agrees in all described characters. Specimens of *H. inermis* of a similar large size were also taken by the Galathea in the Indian Ocean. The specific validity of *H. giganteus* at any rate needs confirmation by additional material.

Hyphalaster scotiae Koehler, 1907

KOEHLER 1907 p. 144 (nom. nud.), 1908 pp. 562-565 (226-229), pls. 6_{60}, 7_{71-72}.

This species is described from two specimens with R/r 15.5/8 and 20/10 mm, dredged by the Scotia Expedition in the Atlantic sector of the Antarctic (71°22'S, 16°34'W, 2580 m, blue mud and terrigenous deposits); further was taken a juvenile one with R/r only 6/4.5 mm.

The large specimens have 8 superomarginals, higher than long, joining their opposites from no. 5. Five cribriform organs. A conspicuous terminal ossicle with 4 small spines, viz. a dorsal median one besides the usual 3. Small close-set paxillae with 1 central and 6-7 surrounding spinelets. A small apical cone. Adambulacralia with 3 fairly short conical and pointed furrow spines, and 2 rather similar subambulacral ones. Oralia with about 6 spines marginally, 3-4 smaller spines suborally along the suture, and 2-3 spinelets on the main surface. Ventrolateral plates with conical spinelets.

The juvenile specimen has 3 superomarginals and 3(-4) cribriform organs. A conspicuous terminal ossicle, broad and with a proximal notch, with 5 spines, a large distal terminal one, a pair of smaller subterminal ones, and a granuliform spinelet laterally to each side. A small apical cone. The dorsal side with scattered embryonic plates with 1-2 spinelets, and otherwise covered by large granules. Adambulacralia (in a number of 7) with 4 large and flattened furrow spines (in the arms 3 or 2) and 1-2 subambulacral granules. Oralia with 6 marginal spines and 2-3 suboral granules. Ventrolateral plates with a few granules.

This species is near *H. inermis*, but seems distinguished by having larger subambulacral spines, and further by having relatively fewer superomarginal plates, and more armed terminal ossicles.

Abyssaster gen. nov.

Type-species: *Hyphalaster tara* Wood-Mason & Alcock, 1891.

Syn. *Hyphalaster* Sladen pars.

This new genus is erected to receive three species which were formerly included in the genus *Hyphalaster*, viz. *diadematus* Sladen, 1883, *planus* Sladen, 1883, and *tara* Wood-Mason & Alcock, 1891. Of the two former species only a few specimens are known, whereas several specimens are recorded of the third. This species, therefore, has been chosen as the type of the genus.

Diagnosis:

Porcellanasterids with opposite superomarginals separate to terminal ossicle. All superomarginals unarmed. A mid-interradial suture. Cribriform organs (3-5) confined to disk marginals. Each oral ossicle with a proximal, enlarged mouth-spine.

Description:

The specimens of this group have a subpentagonal disk and fairly broad arms which are only slightly tapering. The ratio R/r ranges from less than 2 in the small specimens to about 2.5 in the largest known, with R about 35 mm. The terminal ossicle is distal to the arm end, fairly conspicuous, and with from 3 to several spines. The inferomarginals of the arms are only slightly lower than their superomarginal companions. In well expanded specimens with full stomachs, the marginals form a perpendicular contour to disk and arms, whereas in contracted specimens with the stomach empty, the superomarginals arch over the dorsal side, so that the opposites in the arms may touch each other above the sunken and wrinkled dorsal integument. The dorsal disk area proper is beset with crowded paxillae, arranged with more or less regular radial (perhaps also interradial) patches of large ones among the main uniform armature of smaller ones. There is an apical appendage, also often in the larger specimens, or at least a distinct apical cone. The integument of the arm bases and the arms is armed with a plating of rounded scales. The jaws show a prominent broad keel formed by the interradial part of the two oralia, which meet proximally and medially, with a fairly broad suture between these places of contact. Each oral ossicle carries a series of up to 7 marginal spines, the proximal one the largest, and possibly some spinelets or granules on its surface. The exposed surface of the primary oral ossicle is in the type-species of a transverse narrow appearance. The adambulacralia are subrhomboid or subcrescentic, with an outward curved furrow margin and 4-7 furrow spines (in the type-species flattened lanceolate). The furrow spines form together a wavy continuous series along either side of the narrow furrow. There is generally no subambulacral armature, though some of the proximal adambulacralia may bear a few granules adorally on their surface. The ventrolateral area is paved with scales, which distally are arranged in radiating rows, corresponding two and two with a marginal plate, and which in the large specimens are armed with spinelets or granules, as is also the surface of the oralia and the adambulacralia. In the arms there is only a narrow strip of naked integument between the adambulacralia and the inferomarginalia.

Key to the species of *Abyssaster*

Abyssaster tara (Wood-Mason & Alcock, 1891)
Figs. 8-9. Pl. IV.

Hyphalaster tara n. sp., Wood-Mason & Alcock 1891 *b* pp. 434-435, fig. 11.
Hyphalaster tara, Alcock 1893 p. 86.
Hyphalaster tara, Macan 1938 pp. 329-331.

This species was described from a material (number of specimens not stated) obtained by the Investigator in two dredgings in the Bay of Bengal (st. 110: 9°34′N, 85°43′ E, 3650 m, globigerina ooze, 1.7° C.; and st. 117: 11°58′N, 88°52′E, 3200 m, blue mud, 1.8° C.).

The type-specimen has R/r about 18/9 mm, judging from the figure; 6 superomarginals, which are unarmed and according to the description "hardly meet in the middle line along the ray"; 3 papilliform cribriform organs; terminal ossicle fairly large and with 4 spines, a dorsal median one besides the usual 3. Disk with small paxillae with 3-4 spinelets, and five radial bands of larger paxillae with 10-15 spinelets. (The dorsal armature in the arms is not described. The somewhat schematic figure may seem to indicate the presence of paxillae, but erroneously, since the Galathea specimens show a pavement of naked plates). The type-specimens has a well developed apical appendage. Adambulacralia with a fan-like comb of 5-6 compressed lanceolate furrow spines. Oralia with 7 compressed lanceolate marginal spines, of which the proximal one is much enlarged. Ventrolateral plates broad, imbricating ("in ab. nine columns parallel to radial axis"), and with deciduous spinelets.

Macan (1938) records and describes 15 specimens collected by the John Murray Expedition in the Arabian Sea near the Carlsberg ridge (st. 171: about 9°08′N, 53°30′E, 3840-3872 m). The dimensions of seven of these specimens are given as R/r 20/8 to 25/12 mm. Macan notes that "there are 6 superomarginals of which the distal 4 are in contact with their opposites down the length of the ray," (but as will appear from the description of the Galathea material, this applies only to abnormally contracted specimens). There are 18-24 large paxillae

in each radial group, arranged in 3 irregular rows. In one of the large specimens, the enlarged paxillae are distributed in more groups in each radius, and further there may be two rows of larger paxillae near the margin of the disk. The adambulacralia bear 5-6 flattened triangular furrow spines. The oralia carry 8-9 marginal spines, and in one specimen there are further 5 suboral granules, whereas the oralia in the other specimens have a naked surface. The ventrolateral plates are stated to be devoid of spines. Eight small specimens have R 6-12 mm, 3-4 superomarginalia, 4-6 furrow spines, and 3 terminal spines only.

The Galathea material:

A total of 62 specimens of *Abyssaster tara* were collected in the Indian Ocean in four different dredgings, off Durban, in the Mozambique Channel, off Kenya, and off Ceylon respectively, viz.

St. 193. 32°34′S, 31°52′E, 3680 m, 1.1°C., globigerina ooze. 3 specimens.
St. 217. 14°20′S, 45°09′E, 3390 m, 1.6°C., globigerina ooze. 3 specimens.
St. 238. 3°23′S, 44°04′E, 3960 m, 1.8°C., globigerina ooze. 33 specimens.
St. 282. 5°32′N, 78°41′E, 4040 m, 1.5°C., blackish mud. 23 specimens.

R/r range in the specimens from st. 193 from 16/7 to 18/9 mm, in those from st. 217 from 13/5 to 20/9 mm, in those from st. 238 from 11/6 to 35/15 mm, and in those from st. 282 from 12/6 to 28/12 mm. The specimens from the two latter stations supplement each other as regards size, 22 of the 23 specimens from st. 282 ranging from R/r 12/6 to 23/10 mm, and 31 of the 33 specimens from st. 238 ranging from R/r 26/11 to 35/15 mm. It therefore seems appropriate to describe the available specimens of these two populations separately.

The population from st. 282, off Ceylon, in the vicinity of the type-locality:

These 23 specimens have R/r as follows: 12/6, 12.5/6, 12.5/6.5, 13/7, 13/7, 14/7, 14/7, 14/8, 15/7, 15/8, 16/8, 17/7, 17/7, 17/8, 18/8, 19/8, 19/9, 19/10, 20/9, 21/9, 22/11, 23/10, and 28/12 mm. The ratio R/r thus ranges from about 1.7 to 2.4. It is $\leqq 2$ in specimens with R up to 16 mm, $\geqq 2$ in specimens with R 17-23 mm, and 2.4 in the large one with R 28 mm.

The superomarginal plates (fig. 8*a, i, s*) are subquadrate or slightly longer than high and show a granulated surface. Their number ranges in these specimens from st. 282 from 4 to 6. Four superomarginals may be found in specimens up to a size of R/r 17/7 mm, but 5 is otherwise the usual number of superomarginals in the medium-sized and also in the smaller specimens available. When only 4 superomarginals are present, also the distal one is well developed and reaches up on the dorsal side of the arm in front of the terminal ossicle. If there are 5 superomarginals, the distal one is situated in its whole length below the terminal ossicle, and still rudimentary and triangular. Also specimens as large as R/r 22/11 mm may have only 5 superomarginals in one or more arms, but the distal one is then always well developed. Six superomarginals is otherwise the usual number in the specimens with R/r 19/9 mm or more, and 6 superomarginals may also be found in specimens with R/r only 15/7 mm.

The inferomarginals are typically situated exactly below their superomarginal partners, in the arms they may however, in some cases be somewhat displaced in relation to these. Towards the end of the arms the inferomarginals become gradually lower than the accompanying superomarginals, so that distally they are only about one-third as high as these. Often there is one additional inferomarginal plate at the tip of the arm.

The cribriform organs number 3 in each arm angle; they are of papilliform structure; and also the papillae of the outer covering series are small.

The terminal ossicle is conspicuous, of a rather obtuse globular appearance, and usually with a faint proximal notch, though also sometimes with the proximal margin simply rounded. It is distal to the arm end, and distinctly larger than this. Typically the terminal ossicle is provided with 4 spines (fig. 8*a*): a distal terminal one, a pair of subterminal ones, and a proximal dorsal and median one. This latter spine may be absent, and the terminal ossicle with only 3 spines, which is the case in a specimen with R/r 14/8 mm, but it may also be substituted by a group of a few spinelets or by a pair of spines, one to either side of the median line, or supplemented by such a pair (fig. 9*a, c*). Sometimes there may even be several additional spines on the terminal ossicle, e.g. a spine laterally to either side of the distal terminal one, or two or even three pairs of subterminal spines (fig. 9*e*). The proximal median dorsal spine may be accompanied by a few spinelets adorally, and there may be, as e.g. in the largest specimen, a series of minute spinelets along the lateral ventral margin (fig. 9*h*).

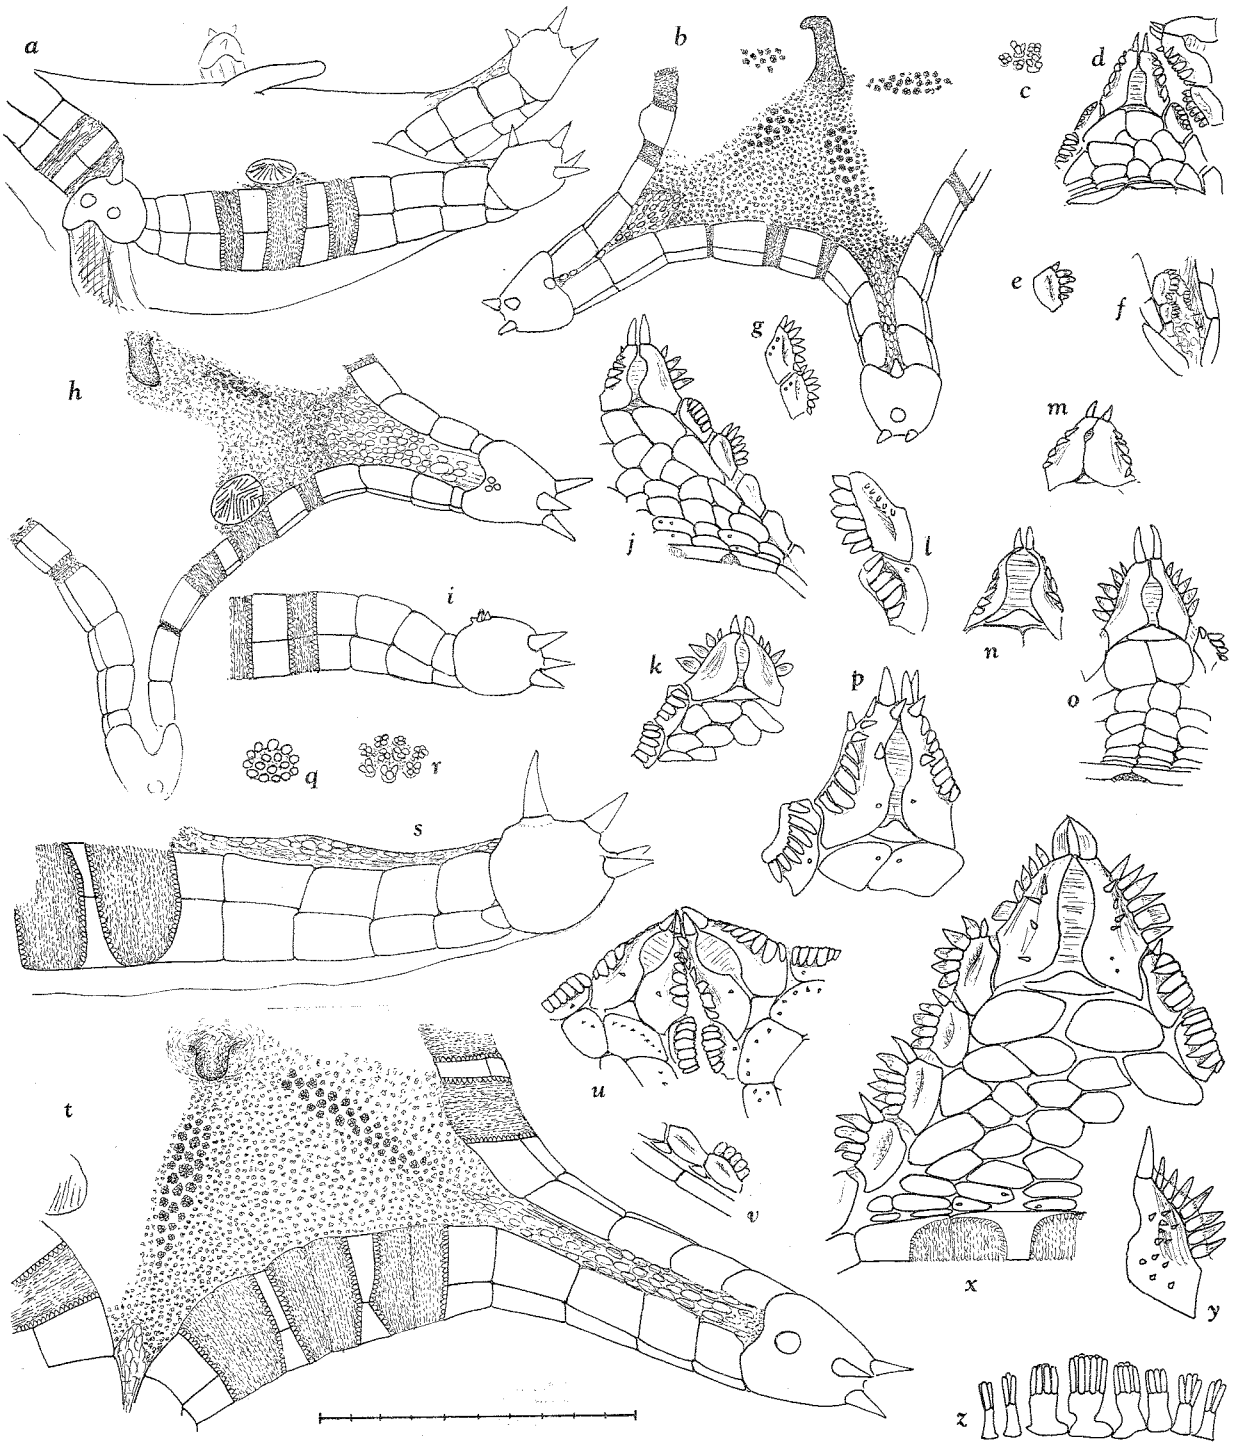

Fig. 8. *Abyssaster tara*. a-f) St. 282, R/r 12.5/6 mm; c, paxillae from near the arm base in four times the usual scale; e, adambulacral ossicle no. 4; f, arm end showing the adambulacralia nos. 7-8. g) St. 282, small specimen, adambulacralia nos. 1-2. h-j) St. 282, R/r 13/7 mm, with four cribriform organs in one interradius; h-i, same arm in dorsal view and in lateral view. k) St. 238, R/r 13/7 mm. l) St. 238, R/r 34/13 mm, adambulacralia nos. 1-2. m) St. 282, r ab. 7 mm. n-o) St. 282, r ab. 9 mm. p) St. 282, R/r 28/12 mm. q-v) St. 282, R/r 23/10 mm; q-r, one of the larger paxillae and a group of the smaller ones in four times the usual scale; s-t, same arm in lateral view and in dorsal view; v, adambulacral ossicle no. 9. x) St. 238, R/r 33/15 mm. y) St. 238, R/r 35/14 mm. z) St. 238, R/r 29/12 mm, paxillae in lateral view, from a tangential line across the disk, showing four enlarged ones and to either side of these the usual smaller ones.
Scale: 10 mm (in c, q, r, and z 2.5 mm).

The central and interradial part of the disk is covered with paxillae, extending as far as to a line connecting the distal end of the second superomarginals, whereas in the arm bases and the arms there is a plating of small rounded plates; the distal ones slightly, or sometimes distinctly larger, and further, more spaced than the proximal ones. The stretch of integument in the arms is in fairly well expanded specimens about half as broad as the terminal ossicle and usually very conspicuous, but in contracted specimens the thin skin of the arms may be sunk and the superomarginal plates almost or actually meeting their opposites above it. This, however, is an artificial state.

The species *tara* has the arms similar to those in SLADEN's *planus* and *diadematus,* which two species it also resembles in other respects. From the type-description of *tara* and from the figure published one might, however, get the impression that *tara* had an armature of paxillae also in the arm bases, and unfortunately MACAN gives no description of the arm armature in his material from the Arabian Sea. Since all other characters agree, it cannot be doubted, however, that the present material represents the species described by WOOD-MASON & ALCOCK.

The paxillae of the main part of the disk are small and generally provided with 3-4 spinelets, this also in the large specimens at hand. The number of spinelets on a paxilla may vary, however, from 2 to 6. Further there are radially arranged groups of larger paxillae, yet hardly discernible in a few of the small specimens (the paxillae in the radial groups here being still only little larger than the others), but already very prominent in other equal-sized small specimens. The patches of enlarged paxillae are more or less distinctly elongate in radial direction, extending a short distance from the center of the disk to usually about the middle of the second superomarginals (fig. 8*t*). In specimens with R/r 13/7 to 14/8 mm the paxillae included in each group number about 7-10 in radial direction and 2-3 across. In the largest specimens the groups of enlarged paxillae likewise number only up to 3 paxillae across, but here there are usually 15 or more paxillae in radial direction. The enlarged paxillae are of diverse sizes within the patches as well as in the different specimens. In a specimen with R/r 23/10 mm the largest paxillae carry up to 16 spinelets.

The paxillar bases form a close pavement in the radial groups of enlarged paxillae, whereas the bases of the other and smaller paxillae of the main part of the disk are spaced. In the present specimens the larger paxillae are often found with their distal part broken off, and then they appear as elongate patches of subhexagonal plates. The smaller paxillae generally have their shafts preserved though they may have lost their spinelets. The reason why the enlarged paxillar shafts are more easily broken than the smaller ones is that they have a marked constriction above the lower part which is attached in the integument. In some of the large specimens, more or less enlarged paxillae are found besides in the radial groups also along the margin of the disk, close to the marginalia or separated from them by a single row of smaller paxillae, and further around the madreporite.

All the specimens at hand have a distinct apical appendage, provided with very minute plates each with one or two minute spinelets.

The madreporic body is subcircular or sometimes transversely oval; in general with the largest diameter about equal to, or a little less than the length of the adjoining marginalia, and with the striae typically radiating from a point quite near the proximal margin. In one specimen, however, it is slightly larger in radial than in tangential direction, and has the striae radiating from an only slightly eccentrical point. The madreporite may lie close to the marginals, or is separated from these by one or sometimes two series of paxillae.

Papulae occur interradially on the disk, but are usually not observable.

The adambulacral ossicles number 10-11 in two specimens with R/r 12.5/6-13/7 mm, 14 in one with R/r 23/10 mm, and 16 in one with R/r 28/12 mm, the number of superomarginals being 5, 6, and 6 respectively. The adambulacralia of the disk area (fig. 8*j, x*) are rather elongate, with an outward curved furrow edge with a comb of generally 5-6 flattened lanceolate and pointed furrow spines which are more or less distinctly curved in abradial direction and have the appearance of segmental papillae at a segmental pit, which extends the whole length of the adambulacral ossicle, and is very distinct on them all, except the distal rudimentary ones below the terminalia. The number of furrow spines occasionally is only 4, as e.g. in a specimen with R/r 17/7 mm, or as many as 7, as e.g. in the two largest specimens, with R/r 23/10 and 28/12 mm. In general there is no subambulacral armature, but some of the most proximal adambulacral ossicles in the larger specimens may adorally on their surface be provided with a single or sometimes 2 or 3 granules.

The oral ossicles of each pair forming a jaw (fig. 8*d, j, m-o, p, u*) are separated by a broad suture and are widely divergent distally where they expose the very broad primary oral ossicle. Each oralia has at its proximal end a large slightly flattened blunt or pointed mouth-spine, and bears along its lateral margin a series of from 3 to 8(-9) smaller spines, the distal ones being larger than the proximal ones. The proximal one to three of these lateral oral spines are often rather spiniform, whereas the more distal ones are distinctly flattened, broad, pointed or blunt, and appear as a series of segmental papillae (see p. 42).

In the small specimens the number of marginal oral spines, inclusive of the large proximal one, is generally 6-7, but may be only 5-6, as e.g. in a specimen with R/r 16/8 mm, or 4-5, as e.g. in a specimen with R/r 17/7 mm. In the large specimens, with R/r 19/9 mm or more, there may be from 6 to 8 oral spines. In the largest specimen available, R/r 28/12 mm (fig. 8*p*), there is even a marginal series of up to 9 spines; and close to the large mouth-spine there may be two additional, slightly smaller spines, below and above it respectively. On the ventral surface of the oralia this specimen may further have a conical spine medially at the suture, and 1-2 granules distally. There may also be a small spine on the inner side of the oral ossicle facing the oral cavity.

The ventrolateral area is covered with a pavement of scales arranged in tangential rows, 6-7 in the small specimens and up to 9-10 in the large ones, and further also in radial series, corresponding two and two with a marginal plate; distally thus in about 8 series, as the ventrolateral plates generally extend to the outer corner of the second inferomarginal plate, or sometimes, when the ventrolateral plates extend as far out as to the proximal part of the third inferomarginals, in 10 series. In the proximal tangential row, at the jaw, the ventrolateral plates number 2, or possibly 3 or 4, and are rather large and irregularly polygonal in shape. The ventrolateral plates in the following tangential rows may also be irregularly shaped, and the radial arrangement in consequence lost. The more distal ventrolateral plates are transversely elongate or subhexagonal in shape, sometimes regularly broadly hexagonal; and usually they are slightly imbricating.

The ventrolateral plates are generally all naked in the small specimens, whereas in specimens with R about 15 mm or more, some of the distal plates usually are provided with a few granules. One specimen with R/r 23/10 mm (fig. 8*u*) has granules also on the proximal plates, in a number of up to about six on the larger ones. In the largest specimen, with R/r 28/12 mm, all the ventrolateral plates appear naked however.

In the arms there is a narrow strip of naked skin between the adambulacral ossicles and the inferomarginals, and the ends of the adambulacral ossicles may be discernible between successive adambulacralia.

The population from st. 238, off Kenya:

These 33 specimens of *Abyssaster tara* have R/r: 11/6, 13/7, 26/11, 27/11, 27/11, 27/12, 29/12, 29/13, 29/13, 30/11, 30/13, 30/13, 30/14, 30/15, 31/13, 31/14, 32/12, 32/12, 32/13, 32/13, 32/13, 32/13, 32/15, 33/13, 33/14, 33/15, 33/15, 34/13, 35/13, 35/14, 35/14, 35/15, and 35/15 mm. The ratio R/r thus ranges from about 2.2 (R 27-33 mm) to 2.7 (R 30-35 mm).

The superomarginals are present in a number of 5 in specimens with R 11-13 mm, 6 in specimens with R 26-27 mm, 7 in specimens with R 29-33 mm, 8 in specimens with R 32-35 mm, and 9 in a few of the largest specimens with R 35 mm. When the number of superomarginals is relatively large in relation to the length of the arms, the distal superomarginal plate is as a rule still rudimentary and situated entirely below the terminal ossicle. The opposite superomarginals remain separate, also in the largest specimens, throughout the whole length of the arms. The inferomarginals as usual are often distally one more in number than the superomarginals.

The cribriform organs are typically present in a number of three in each interradius, the larger organs comprising up to 28-30 rows of papillae. The largest specimens, however, may sometimes be provided with a rudimentary additional cribriform organ to one or to both sides in one or more of the interradii, yet only developed around the suture between the superomarginals. One specimen with R/r 32/15 mm e.g., has 5 cribriform organs in three of the interradii. The 3 median cribriform organs may almost coalesce in the larger specimens.

The terminal ossicles may be even more conspicuous in these large specimens than they were in the above described somewhat smaller specimens from st. 282, although the general rule is that the terminal ossicles become less conspicuous with age. Some of the largest specimens present, with R/r e.g. 33/13 and 35/14 mm, may have the terminal ossicles

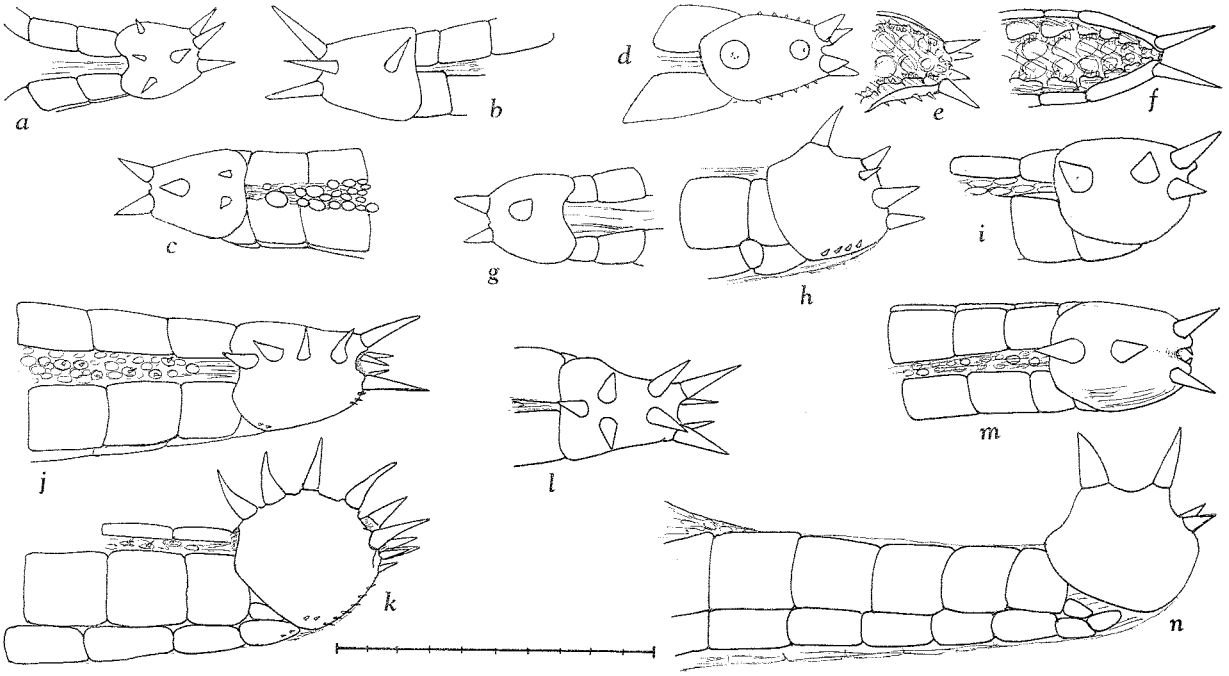

Fig. 9. *Abyssaster tara*. Terminal ossicles; a, st. 282, R/r 16/8 mm; b, st. 193, R/r 18/9 mm; c, st. 282, R/r 19/9 mm; d-e, f, g, h, i, st. 282, R/r 28/12 mm; j-k, st. 238, R/r 32/15 mm; l, st. 238, R/r 30/13 mm; m-n, st. 238, R/r 33/13 mm. Scale: 10 mm.

armed only with the 4 usual spines (fig. 9*m-n*), which are also present in the smallest specimen, with R/r 13/7 mm. Several of the specimens, however, have a much denser armature on the terminal ossicles.

Variations in this armature not met with in the specimens from st. 282 are e.g.: a median row of up to 3 additional spines on the dorsal side of the terminal ossicle, (fig. 9*j-k*); the usual single distal terminal spine replaced by 2 spines in a transverse row, and one or two additional pairs of subequal spines dorsally, or one pair and an unpaired medially placed spine. As in the specimens from st. 282 there may be up to three pairs of subterminal spines (3 spines to each side of the furrow end), and in some few cases the terminal ossicle is furnished with a series of minute spinelets along the ventral margin. The spines on the terminal ossicles may be rather stout, short conical and sometimes with a fairly abrupt tip; but they may also be rather long and slender.

The enlarged paxillae in the radial patches may bear up to 20 spinelets in some of the large specimens from st. 238. But in other specimens the paxillae are less distinctly enlarged. In one specimen with R about 30 mm e.g., the paxillae of the main part of the disk carry (3)4-5 spinelets while the 20-25 enlarged paxillae in the radial patches carry from 6 to 10 spinelets. In the large specimens the radial patches of enlarged paxillae (fig. 8*z*) number 2-3 (rarely 4) paxillae across and from about 6 to 15 in radial direction. In a specimen with R/r 30/14 mm there are e.g. in each radius about 3-4 × 7 enlarged paxillae with up to 9 spinelets. In another specimen, with R/r 35/14 mm, the patches of enlarged paxillae are 2-3 paxillae broad and reach practically to the arm-bases, the enlarged paxillae carrying from about 6 to 12 spinelets, while those of the main part of the disk carry 3-4(5) spinelets. Some specimens also have 1-3 series of enlarged paxillae along the margin of the disk.

The enlarged paxillae, as it appears from the small specimens with R/r 13/7 mm, initially are developed around 5 radial primary plates which later are absorbed.

In the specimens with R 32 mm or more, some of the dorsal rounded (or subhexagonal) plates in the arms may bear a single spinelet, and those of the arm bases sometimes 2 spinelets. In these large specimens the limit between the paxillae-bearing disk area and the plate-armed arm bases thus may be rather obscured. In the large specimens there are also distally several plates in a transverse direction across the arms, while 1-2 across is the usual in the small specimens.

These specimens from st. 238 have in general a distinct, though short apical appendage, but in

some of the large specimens there is only an apical cone, and e.g. in one specimen with R/r 35/15 mm hardly any central prominence is discernible.

Papulae are observed interradially in a few of the specimens.

The adambulacral armature consists of 5-6, occasionally only 4 furrow spines, flattened, more or less curved abradially, typically lanceolate, but the 2-3 median ones often very broad (shovel-like). The proximal adambulacral ossicles carry also sometimes a few granules adorally on their surface.

The oral ossicles (fig. 8*k, x, y*) carry from 5 up to 8 marginal spines and often also a number of suboral granules or spinelets. One specimen with R/r 35/14 mm e.g., has thus about a dozen suboral granules (fig. 8*y*). But specimens as large as R/r 30/13 mm may also have oral ossicles with a naked surface. Sometimes one or more of the distal marginal oral spines are distinctly enlarged. In one specimen with R/r 32/15 mm e.g. the most distal marginal oral spine but one is always very broad and 3-dented.

The ventrolateral plates are arranged in up to 7-9 tangential rows. Those near the margin often bear spiniform granules; and granules may occur also over the greater part of the ventrolateral area, e.g. in a number of about 5 to each of the large proximal plates. Other large specimens, however, apparently may be entirely devoid of ventrolateral spinelets.

The specimens from st. 193 (R/r 16/7, 17/8.5, 18/9 mm) and st. 217 (R/r 13/5, 18/9, 20/8.5 mm) fall mainly within the variation recorded in the materials from sts. 282 and 238. The material from st. 217 shows, however, that 3 terminal spines only may be found also in specimens as large as with R/r 20/9 mm, and further that also specimens of this size may show an additional rudimentary cribriform organ in some interradii.

Remarks:

A diameter of 70 mm (R 35 mm) probably is about as large a size as is attained in the species *Abyssaster tara,* since one of the specimens of that size (R/r 35/14 mm by an empty stomach, 8 superomarginalia and 18 adambulacralia) shows a character which may be interpreted as one of senescence, viz. a tendency of the adambulacral furrow to grow beyond the terminal ossicle.

One of the specimens from st. 238, R 33 mm, was infested with three specimens of *Myzostoma,* attached to the paxillae near the margin.

Yet unripe eggs, 0.35 mm in diameter, filled the gonads of a specimen from st. 238 with R/r 34/16 mm. The gonads open near the middle of the first superomarginal plates, at the outer corner of the cribriform organs.

Distribution:

Abyssaster tara has been dredged in seven localities in the Indian Ocean, scattered along the whole East African coast, and in the region of the Bay of Bengal (fig. 32), at depths from 3200 to 4040 m, on a bottom of globigerina ooze and mud, and at temperatures of 1.1°-1.8° C. The species has further been taken in the North Pacific by the Vitjaz at a depth of 6270-6280 m (BELYAEV in press).

Abyssaster diadematus (Sladen, 1883)

Hyphalaster diadematus n. sp., SLADEN 1883 pp. 237-239; 1889 pp. 159-162, pls. 21_{1-4}, 28_{17-20}.

This species was described from two specimens dredged by the Challenger off Chile (st. 299: 33°31'S, 74°43'W, 3950 m, blue mud, 1.8° C.).

The type-specimen has R/r 24/10 mm; 10 unarmed superomarginalia, longer than high; 5 cribriform organs. Terminal ossicles with 3 spines. Disk with rather spaced pseudopaxillae with 3-4 spinelets, besides radial irregular groups of about 10 larger paxillae with about 10 spinelets, and interradial groups of a few other large paxillae. An apical cone. Arms from base to terminal ossicle with an integument with small naked plates. Adambulacralia with 4 flattened furrow spines and 5-6 subambulacral granules. Oralia with 6-8 marginal spines, and 6-12 suboral granules. Ventrolateral plates subhexagonal and with 5-6 granules.

The other specimen (that figured on pl. 28) has R/r 14/7.5 mm and 7 superomarginals. Only a small number of enlarged paxillae in rather irregularly arranged groups around the well developed apical appendage; only the most proximal adambulacralia with a few subambulacral granules; and only a few granules on the ventral plates.

A. diadematus seems to be distinguished from *A. tara* primarily by a larger number of marginal plates in relation to size, and by a larger number of cribriform organs.

Abyssaster planus (Sladen, 1883)

Hyphalaster planus n. sp., SLADEN 1883 pp. 242-245, 1889 pp. 165-167, pls. 25_{1-3}, 28_{9-12}.

The single specimen on which this species was based was dredged by the Challenger in the southern Indian Ocean (st. 157: 53°55'S, 108°35'E, 3566 m, diatom ooze, 0° C.).

R/r 35/15 mm; 10-11 unarmed subquadrate superomarginals; 7 cribriform organs; terminal ossicle with 3 spines. Disk with paxillae with 4-6 spinelets (-8 according to figure). Arms from base to terminal ossicle with a dorsal integument with squamiform plates. An apical cone. Adambulacralia with 5-6 flattened furrow spines (4 distally), apparently with a pit on the surface, and with a series of 3-5 subambulacral granules. Oralia with 7 marginal spines and a few suboral granules. Ventrolateral area with oblong squamiform plates, and scattered small granules.

A.planus is likewise distinguished from *A.tara* primarily by a larger number of cribriform organs, and a larger number of superomarginals in relation to size.

Whereas the two forms, *A.diadematus* and *A.planus,* appear to be distinct from *A.tara,* they are, on basis of the descriptions alone, not to be distinguished from each other by any convincing characters, and might well prove to be identical.

Lysaster Bell, 1909

Type-species: *Lysaster lorioli* Bell, 1909.

Diagnosis:

Porcellanasterids with superomarginals forming a complete casing to arms. Superomarginals of disk unarmed, but some in arms with a dorsal spine. A mid-interradial suture. Cribriform organs (7) confined to marginals of disk.

Description:

The disk is pentagonal and the arms are gradually tapering. The cribriform organs are papilliform. The inferomarginals in the arms are only about one-third lower than their superomarginal companions. The terminal ossicle is fairly inconspicuous and dorsal to the arm end. The ratio R/r is a little more than 2 when R about 55-60 mm. The whole dorsal side is closely beset with well-developed paxillae. The furrow spines form a continuous wavy series along the narrow furrow. The ventrolateral plates, and the surface of the oralia and the adambulacralia, are armed with spinelets. The general appearance of the genus is like that of *Hyphalaster* and of *Thoracaster*.

Only 1 species.

Lysaster lorioli Bell, 1909

BELL 1909 p. 21, pl. 3.
FISHER 1919 p. 43.
A. M. CLARK 1952 pp. 945-949, text-figs. 1-3.

BELL in 1909 erected this species and genus for two specimens obtained by STANLEY GARDINER near Mauritius at a depth of at least 500-600 fms. ($\eqslantless$ 1000 m). BELL only gave a short diagnosis accompanied by photos of one of the specimens, and erroneously he registered the form as a pentagonasterid (= goniasterid), not recognizing the cribriform organs, though observing that "the granulation on the margin is so regular that the median suture is often obscured".

FISHER in 1919, after having re-examined the type-specimen, published a more exhaustive description of it. He noted its porcellanasterid habit and considered it a close relative of *Thoracaster*.

Finally A. M. CLARK in 1952 published a detailed description of the two specimens, still the only ones known.

The two specimens have R/r 57/26 and 55/25 mm; 11 superomarginals, joining from plates no. 4 (in the type), and some in arms with a short conical erect dorsal spine; 7 cribriform organs. Terminal ossicle covering two rudimentary superomarginals, and with 3 short spines. Disk with a fairly uniform armature of paxillae with 1-8 central and 8-15 peripheral short spinelets. No apical prominence. Ventrolateral plates probably confined to disk area, and each with about half a dozen short conical spinelets. Adambulacral ossicles rectangular (numbering about 20-21, judging from the photo of the type-specimen), proximal ones with 4 subequal, rather stout pointed furrow spines, and 3 smaller subambulacral spines; distal ones with up to 6 subambulacral spinelets in two irregular longitudinal rows. Oralia with 5-7 marginal spines, that at he tip the largest, and 7-8 suboral spines similar to the distal marginal ones.

Remarks:

A. M. CLARK regards, as also did FISHER, *Lysaster* as most nearly related to *Thoracaster,* which,

however, the present author considers at variance with the presence in *Lysaster* of a marginal suture mid-interradially, where in *Thoracaster* there is an odd marginal plate. *Lysaster* rather appears to be related to *Hyphalaster* sensu stricte. *(Thoracaster* and *Hyphalaster,* however, are in most respects very much alike). What primarily distinguishes *Lysaster* from *Hyphalaster* is that its superomarginal spines seem confined to the arms, whereas in *Hyphalaster* they are confined to the superomarginals of the disk, if present at all. *Lysaster* is further distinguished by its smaller number of superomarginals, and by the low ratio of R/r, only little more than 2 in large specimens.

Benthogenia Fisher, 1911

Type-species: *Benthogenia cribellosa,* Fisher 1911.

Diagnosis:

Porcellanasterids with arms encased by superomarginals, each with a dorsal spine, while those of arm angle are unarmed. A mid-interradial suture. Cribriform organs around all vertical marginal sutures, clear to terminal ossicle.

Description:

The disk is subpentagonal with the gradually tapering arms springing from a fairly wide base, the first joining opposite superomarginals being much larger than those bounding the disk. The inferomarginals of the arms are distinctly lower than their superomarginal companions. The cribriform organs are papilliform. The terminal ossicle is dorsal to the arm end, and provided with several spines. R when 78 mm, is about $2^1/_2$ r. The whole dorsal side is armed with close-set well-developed paxillae. The adambulacral spines form a continuous wavy series along the narrow furrow. The jaws are prominent, with a wide suture; and each oral ossicle carries a series of marginal spines. The whole ventral surface inclusive that of the oralia and the adambulacralia, is closely armed with spinelets. The general appearance of the genus is rather like that of *Hyphalaster,* and of *Thoracaster.*

Only 1 species.

Benthogenia cribellosa Fisher, 1911

FISHER 1911 *a* pp. 415-417.
FISHER 1919 pp. 39-4 3, pls. 1_1, 2_1, 8_2.

This species and genus was described from a single specimen collected by the Albatross in the Philippine region (st. 5513: 8°17'N, 124°03'E, 925 m, gray mud and fine sand, 11.5° C.). FISHER in 1919 gave a more thorough description of the same specimen, and also published some figures, and further he recorded three juvenile specimens of the genus from another dredging in the region (Albatross st. 5425: near Cagayanes Island, Sulu Sea, 905 m, gray mud and coral sand, 9.7° C.).

The type-specimen has R/r 78/30 mm; 17 superomarginals, contiguous along midline of arm from plates no. 6, higher than long, and those of first joining pair much the largest. Each superomarginal plate in arms with a short conical dorsal spine. Cribriform organs around every vertical marginal suture, and also extending up on dorsal surface of arms. Terminal ossicle entirely dorsal to arm end, elliptical and with up to 7 spines, viz. a row of 3 in the median dorsal line and 2 to either side distally. Paxillae with 5-15 central and 15-20 peripheral spinelets. Papulae numerous. No apical appendage. Adambulacral ossicles subrectangular, with 7-8 compressed furrow spines, and 10-12 subambulacral spinelets in about two longitudinal series. Number of adambulacralia probably not much larger than that of marginalia. Oral ossicles with 12 marginal spines, the proximal lanceolate one much the largest, and about 15 suboral spinelets in two irregular series. Ventrolateral plates extending nearly to end of arms, those of disk area slightly imbricating and with 5-12 spinelets.

The juvenile specimens range from R 5.5 mm and 4 superomarginals to R 12 mm and 10 superomarginals. In the large one the superomarginals join from the sixth opposite pairs, and one or two in arms bear a dorsal spine. Terminal ossicle with 4 spines, and only with its distal half overlying the superomarginals. Cribriform organs at every marginal suture, but those of arms yet rudimentary. Dorsal paxillae with only 4-5 spinelets. A prominent apical peduncle. Adambulacralia with 5 furrow spines and 0-2 subambulacral spinelets. Oralia with 8 marginal spines and a few suboral spinelets. FISHER notes that he is not quite sure that the juvenile specimens of *Benthogenia* really belong to the species *cribellosa,* which, however, there seems no reason to doubt.

According to FISHER, *Benthogenia* probably is nearest *Hyphalaster.* And that it is closely related to this genus cannot be questioned, but its nearest relative among the other porcellanasterid genera, however, seems to be *Lysaster. Benthogenia* and *Lysaster* both have a low number of superomargi-

nals, and both possess superomarginal arm spines, and appear to differ primarily by the cribriform organs being developed around all the vertical sutures in the former, but in the latter only around the interbrachial ones. In *Benthogenia* the inferomarginals also are comparatively much lower than in *Lysaster*.

Thoracaster Sladen, 1883

Type-species: *Thoracaster cylindratus* Sladen, 1883.

Syn.: *Pseudaster* E. Perrier, 1885 (type-species: *Pseudaster cordifer* Perrier, 1885 = juv. *Thoracaster cylindratus* Sladen).

Diagnosis:

Porcellanasterids with superomarginals forming a complete casing to arms, devoid of larger spines, but possibly covered with minute spinelets. An unpaired superomarginal and accompanying inferomarginal plate in the interradial midline. Cribriform organs generally confined to marginals of disk.

Description:

The disk is subpentagonal with the arms well set off, cylindroid and gradually tapering. The cribriform organs are papilliform. The inferomarginals of the arms are about two-thirds to half as high as their superomarginal companions. The terminal ossicle is fairly inconspicuous and rather distal to the arm end. The ratio R/r ranges from about 2 in small specimens to almost 4 in some of the large ones with R about 100 mm. The shape is rather flat even when the stomach is well filled. The whole dorsal side is armed with crowded well-developed paxillae. The adambulacralia are subrhomboid or subrectangular, with the furrow margin only slightly curved, and with a series of furrow spines connected by a basal web and together forming a continuous almost straight series along the narrow furrow. The jaws are moderately prominent. The oralia meet proximally, and medially, and each carries a series of marginal spines, the proximal one of which is somewhat enlarged. The ventrolateral area is paved with fairly small imbricating plates, and small ventrolateral plates extend down the arms. The whole ventral side, including surface of oralia, primary oral ossicle and adambulacralia, is covered with spinelets. The marginalia may be almost uniformly covered with minute spinelets.

Only 1 species.

Remarks:

SLADEN erected *Thoracaster* for his species *cylindratus*, and two other species have later been described, viz. *T. magnus* by LUDWIG in 1907, and *T. alberti* by KOEHLER in 1909. The form *Pseudaster cordifer* of E. PERRIER 1885 has proved to be based on a juvenile *Thoracaster cylindratus*, and also the specimen listed by CHUN in 1900 as *Hyphalaster valdiviae* n. sp. (on the basis of LUDWIG's preliminary identification), and the specimen mentioned by RICHARD in 1903 as *Hyphalaster* n. sp., have been found to belong to *Thoracaster cylindratus*.

Thoracaster resembles *Benthogenia*, *Lysaster*, and *Hyphalaster* in general appearance, but is, among other things, characterized by having an odd superomarginal and accompanying inferomarginal plate in the interradial midline instead of a suture as in all the other porcellanasterid genera hitherto described.

(Another genus, *Vitjazaster*, from the western North Pacific, which will be described by BELYAEV, agrees with *Thoracaster* in having an odd marginal plate in the interradial midline, but is well distinguished by other characters, e. g. by the appearance of the ventrolateral armature and by having the arms provided with an armature of dorsal plates).

The genus *Thoracaster* has hitherto been recorded from 12 localities, in the tropical Atlantic, in the Indian Ocean, and in the eastern Pacific respectively, in a total of 26 specimens. The Galathea Expedition brought back 37 specimens from seven dredgings in the Indian Ocean, and the infraspecific variation found in this large material has convinced the present author that all recorded specimens of *Thoracaster* belong to one and the same species.

T. cylindratus was described by SLADEN from a single specimen dredged by the Challenger in the eastern Atlantic near the Cape Verde Islands (st. 89: 22°18′N, 22°02′W, 4390 m, globigerina ooze, 2.6°C.). It has R/r 62/21 mm; 21-22 unarmed superomarginals to each side of the unpaired interbrachial one, slightly higher than long, and, judging from the figures, joining from nos. 7-8 (not counting the unpaired plate); 14 cribriform organs. Terminal ossicle inconspicuous, naked. Dorsal area with closely crowded small paxillae with 6-10 spinelets. Adambulacralia with 5 subequal furrow spines, and two irregular rows of about 3 and 5 subambulacral spinelets. Oralia with 6-7 subequal marginal spines and a larger number of suboral spinelets. Ventrolateral plates with a close covering of minute subspiniform granules. (The description of the furrow spines as short and flat apparently only refers to their distal part, protruding outside the thick basal web connecting them).

Pseudaster cordifer: E. PERRIER (1885, 1894) described this form from a single specimen collected by the Talisman near the Azores (st. 134: 42°19′N, 23°36′W, 4060 m, soft, white mud). It has R/r 9/6 mm; 4 superomarginals to either side of an unpaired interradial one; 5-6 inferomarginals; 8 rudimentary cribriform organs. Terminal ossicle broad, with a proximal notch and 3 small spines. Dorsal area with "a regular granulation". A small apical appendage. Adambulacralia rectangular, with 4-5 furrow spines and 3-4 subambulacral spinelets. Oralia with 7 marginal spines, 3-4 suboral spinelets along the suture and 3 distally. Ventrolateral plates with a few minute spinelets.

PERRIER in 1894 in a foot-note says that the presence of an unpaired interradial marginal plate was very remarkable for a porcellanasterid, and might perhaps be an individual anomaly in the described specimen. He had thus overlooked that SLADEN already had described this feature from *Thoracaster cylindratus.*

LUDWIG (1907 p. 313) stated that *Pseudaster cordifer* was a juvenile *Thoracaster cylindratus,* – on basis of his knowledge of the variation with age in *Thoracaster* from his own material from the Pacific, including specimens ranging from R 20 to 98 mm (cf. below). (Juvenile specimens of *Thoracaster* agreeing with the description of *Pseudaster cordifer* are also present in the Galathea material).

A specimen of *Thoracaster* was collected by the Valdivia Expedition in a dredging off Liberia (st. 45: 2°56′N, 11°40′W, 4990 m, yellow-brown mud, 2.4°C.) not far away from the type-locality of *T. cylindratus.* Ludwig preliminarily considered it as representing a new species of *Hyphalaster,* for which reason it was listed under the name of *Hyphalaster valdiviae* (a nom. nud.) by CHUN in 1900. In 1907 p. 313 LUDWIG, however, stated that the specimen in question in fact belongs to the species *Thoracaster cylindratus.* A detailed description of it was finally given by LIEBERKIND in 1932. It has R/r 67/21 mm; 22 superomarginals to each side of the unpaired median one; 13 fully developed cribriform organs and a few rudimentary ones; naked terminalia. It shows a slight variation from the type-specimen by having minute plates inserted here and there between the otherwise joining superomarginals proximally in the arms.

Thoracaster cylindratus was further recorded by KOEHLER (1909*b*) from two Princesse Alice dredgings near the Azores (st. 753: about 39°50′N, 18°W, 4360 m, globigerina ooze, and st. 1306: about 37°17′N, 20°13′W, 4275 m, globigerina ooze), 3 and 1 specimen respectively. The latter specimen was preliminarily listed by RICHARD (1903 p. 66) as *Hyphalaster* n. sp., and the station by a lapse given as st. 1036. The three specimens from st. 753 had R/r 75/22, 76/22, and 80/23 mm; 25/26 superomarginals to each side of the unpaired one, and 14 cribriform organs. The specimen from st. 1306 is a juvenile with R/r 12/7 mm, 7 superomarginals to each side of the unpaired one, 6 cribriform organs, terminal ossicle with 3 spines. It corresponds, as KOEHLER notes, in general appearance to the specimen described by PERRIER as *Pseudaster cordifer.*

Two specimens of *Thoracaster cylindratus* were recorded by the present author (1951) from a dredging of the Swedish Deep-Sea Expedition in the western tropical Atlantic (st. 342: about 2°25′N, 39°19′W, 4474-4430 m, calcareous clay, 1.3°C.). They have R/r about 43/14 and 46/16 mm, 18 and 20 superomarginals besides the unpaired one, and 12-13 and 13-14 cribriform organs.

Thoracaster magnus: This form was described by LUDWIG in 1907 on the basis of 9 specimens collected by the Albatross in four dredgings in the tropical eastern Pacific off Peru (st. 4647: 4°33′S, 87°43′W, 3667 m, globigerina ooze, 1.9°C.; st. 4649: 5°17′S, 85°20′W, 4088 m, grey mud, 1.9°C.; st. 4658: 8°30′S, 85°36′W, 4335 m, green mud, 1.8°C.; and st. 4717: 5°11′S, 98°56′W, 3938 m, globigerina ooze, 1.8°C.). The same material was described and figured by H. L. CLARK in 1920. R/r range from 23/? to 98/32 mm. Specimens with R 72-98 mm have 22-24 superomarginals besides the unpaired one, and 14 cribriform organs. Terminal ossicles inconspicuous and with a pair of small spines ventrally. Dorsal paxillae with up to 30 spinelets. Small plates proximally in the dorsal midline of the arms, between the opposite superomarginals. Papulae interradially. Ambulacralia with 4-5 furrow spines and 3-4 smaller subambulacral spines. Oralia with 8 marginal spines and 10-12 smaller suboral ones. Ventrolateral plates, according to LUDWIG, with a more robust, but sparser spine-armature than in *T. cylindratus*.

LUDWIG states as the character primarily distinguishing *T. magnus* from *T. cylindratus* that the superomarginal plates of both sides of the arms only join immediately in the distal part, whereas in the proximal part they are separated by a series of minute plates. As other distinguishing features LUDWIG mentions the larger number of paxillar spinelets, the broader cribriform organs, and the more robust ventrolateral spine armature. All these differences, however, are accounted for by the larger size of several of the specimens of *T. magnus*.

H. L. CLARK in 1920 p. 79, gave a more detailed description of the appearance of the dorsal arm plates and their distribution in *Thoracaster magnus*. He writes e. g.: "In a specimen with R = 23 mm. this series (i. e. of abactinal plates which extends to the tip of the arm or nearly so) is .60 mm wide clear to the terminal plate; ... In a large specimen, with R = 73 mm., the plates do not reach the extreme tip of the arm, but are shut off from the terminal plate by the meeting of three pairs of superomarginals; ...".

LIEBERKIND, as mentioned above, found some minute plates inserted between the opposite superomarginals proximally in the arms of the Valdivia specimen of *T. cylindratus*, for which reason he began to doubt the specific validity of *T. magnus*. He re-examined one of the original specimens of this form and found only some unimportant differences from the type of *T. cylindratus*, e. g. in the appearances of the spinelets of the dorsal paxillae and of the cribriform organs. LIEBERKIND noted also that he was inclined to believe that a larger material would show intermediate characters, the two forms in question in reality being only two geographical races of the same species; but, nevertheless, he considered it the most appropriate provisionally to retain them as separate species.

Incidentally, LIEBERKIND makes a lapse in his discussion of the forms of *Thoracaster* described. He refers, p. 287, to H. L. CLARK's statement, op. cit. p. 79, that "In another particular, *magnus* differs markedly from the other two species of the genus (*cylindratus* and *alberti*), and that is in the series of abactinal plates which extends to the tip of the arms ...". And then he claims that CLARK is not right in considering this a difference from *T. cylindratus* since, he says, the figures SLADEN gives, distinctly show the same feature although SLADEN does not mention it in his text. This remark, however, is only understandable if it is assumed that LIEBERKIND has misread "abactinal" in CLARK's text as "actinal", since what he had in mind can only have been the series of ventrolateral plates extending down the arms.

A single, large specimen of *Thoracaster*, collected by the Arcturus in the tropical eastern Pacific (st. 53: 1°51′S, 89°50′W, 3170 m), was recorded by FISHER in 1928 as a *T. magnus*.

The differences between *T. cylindratus* and *T. magnus* stated in the literature appear quite unimportant taxonomically, and when dealing with *Thoracaster cylindratus* in 1951, the present author, therefore, listed *magnus* as a synonym, a view which the study of the specimens collected by the Galathea confirms.

Thoracaster alberti: KOEHLER (1909*a*) described this species from 7 specimens dredged by the Investigator in the Arabian Sea (st. 287: 21°09′N, 65°47′E, 2755 m, green clay, 2.8°C.). R/r 45/17 mm in one specimen, about 60/20 to 60/21 mm in the others; 17-18 superomarginals besides the unpaired one, joining from nos. 5-6 (exceptionally no. 7), subquadrate interbrachially, rectangular in arms; 14 cribriform organs. Median part of the marginals of the disk provided with small pointed spines in 1-3 irregular vertical rows between the cribriform organs; also the proximal arm marginals with an armature of spinelets. Terminal ossicle inconspicuous, with 3 small spines. Dorsal paxillae with 20-30 granules. Sometimes a faint apical cone. Adambulacralia with

4 flattened subequal furrow spines, and 3-4 granuliform subambulacral spinelets. Oralia with about 10 marginal spines (7-8 are shown in the figure 7, pl. 5), and a larger number of suboral ones. Ventrolateral area uniformly covered with spiniform granules.

Thoracaster alberti should be distinguished from *T. cylindratus* by the armature of spinelets between the cribriform organs; but this is a character of uncertain taxonomical value. H.L. CLARK recorded spinelets dorsally and ventrally on the marginals between the cribriform organs also in the material of *T. magnus*. And the present material of *Thoracaster* from the Galathea Expedition has shown that the spine-armature of the marginals is really very variable. The conclusion therefore is that also *T. alberti* is the same species as *T. cylindratus*.

The Galathea material:

A total of 37 specimens of *Thoracaster* was collected in seven dredgings in the Indian Ocean, viz. two off East Africa north of Madagascar, three near Ceylon, and two in the Bay of Bengal.

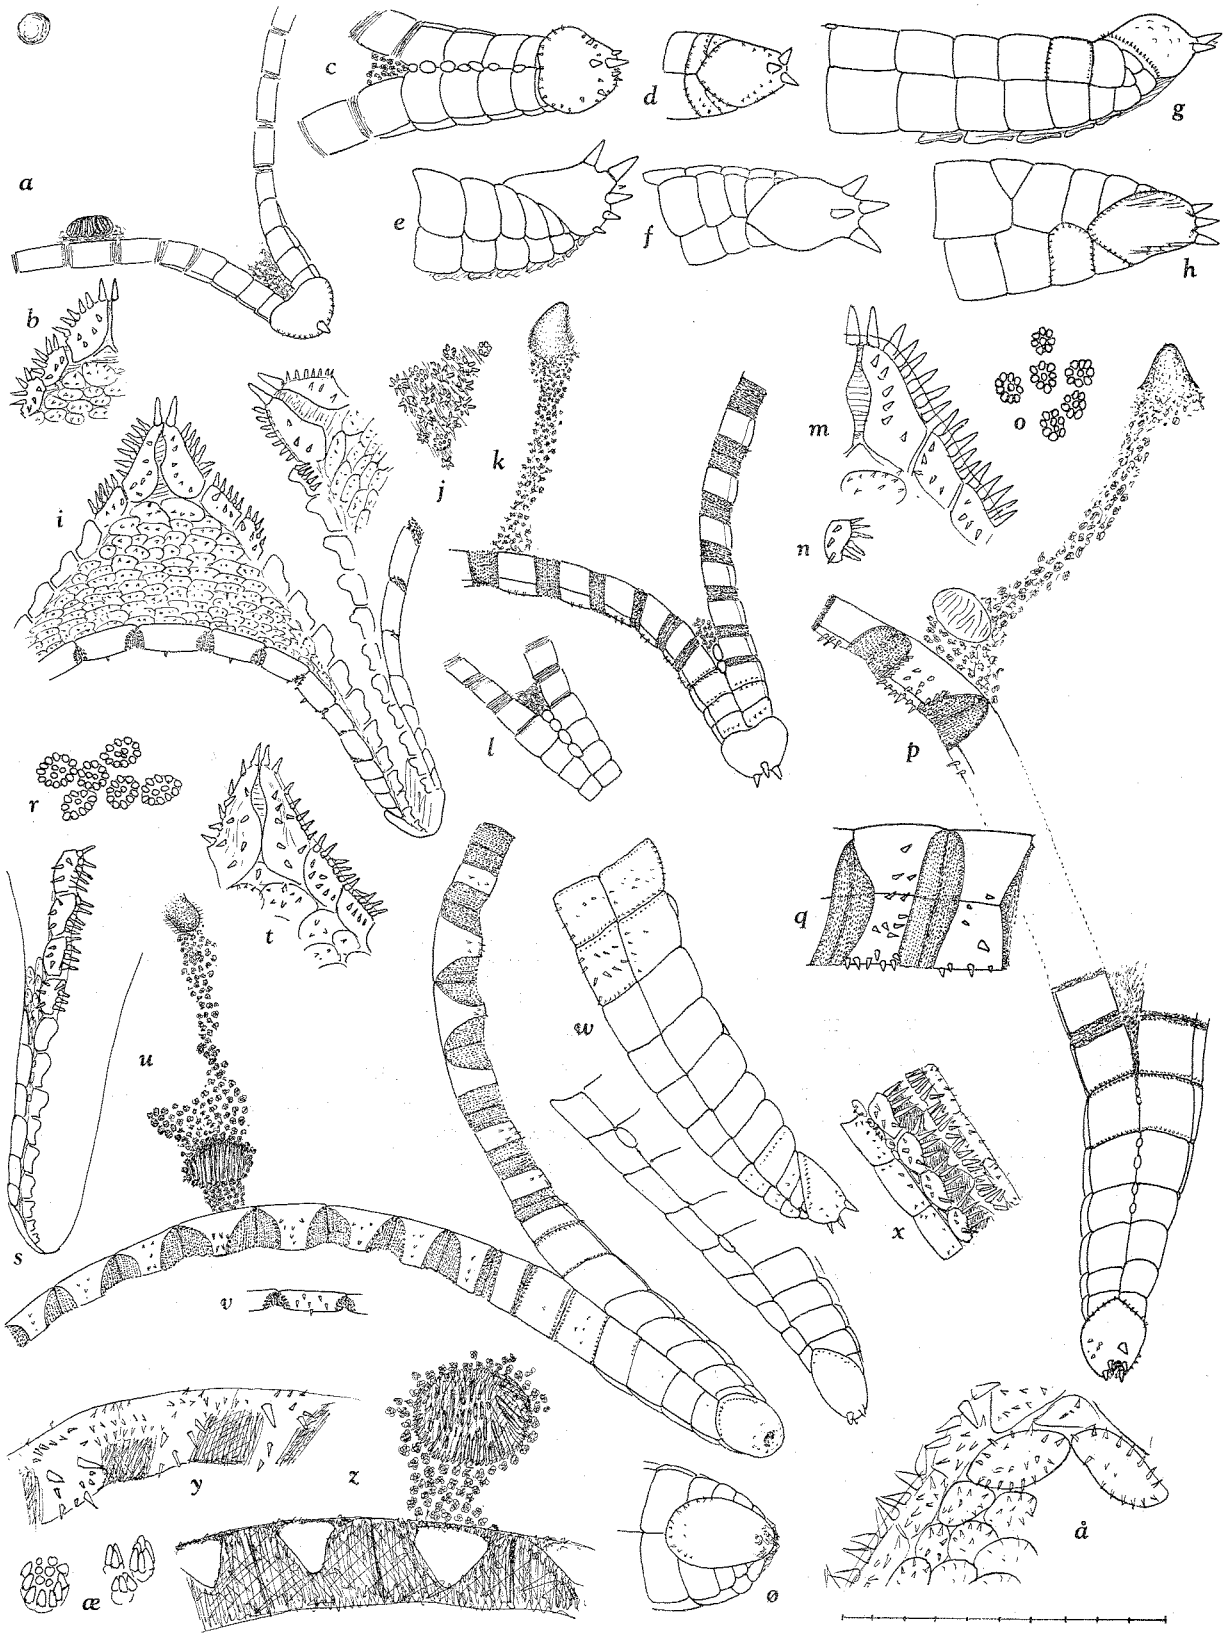
St. 232: 9°03′S, 49°22′E, 4930 m, 1.3°C. 1 specimen.
St. 238: 3°23′S, 44°04′E, 3960 m, 1.8°C., globigerina ooze. 3 specimens.
St. 280: 1°56′N, 77°05′E, 4350 m, 1.3°C., globigerina ooze. 2 specimens.
St. 281: 3°38′N, 78°15′E, 3310 m, 1.8°C., globigerina ooze. 6 specimens.
St. 282: 5°32′N, 78°41′E, 4040 m, ca. 1.5°C., blackish mud. 1 specimen.
St. 299: 17°10′N, 84°30′E, 2820 m, 1.7°C., mud. 1 specimen.
St. 314: 15°54′N, 90°17′E, 2600 m, 1.7°C., brownish ooze. 23 specimens.

The single specimen from st. 232 (pl. VI 7) has R/r 101/30 mm; about 28 superomarginals (not counting the unpaired one), and 22 cribriform organs. The three specimens from st. 238 have R/r 89/28, 100/27, and 103/30 mm, 24, 23 and 24 superomarginals respectively, and 13-14, 11-14 and 12-13 cribriform organs. The two specimens from st. 280 have R/r 84/22 and 86/24 mm, 24 and 25-26 superomarginals, and 14 cribriform organs. The six specimens from st. 281 have R/r 13/7, 20/10, 41/12, 42/12, 64/20, 66/23 mm, and 7, 10, 18, 18, 24, and 21 superomarginals respectively, the two small specimens 4-6 and 8-10, the medium-sized ones 12-14, and the two larger ones 14 and 12 cribriform organs. The single specimen from st. 282 has R/r 87/23 mm, 24-26 superomarginals, and 14-16 cribriform organs. The single specimen from st. 299 has R/r 31/11 mm, 14 superomarginals, and 14 cribriform organs. The material of 23 specimens from st. 314 includes ten juveniles with R/r ranging from 14/6.5 and 14/7 mm to about 24/9 mm, 8 to 10 (11 ?) superomarginals, and 10 to 12 cribriform organs. Another small specimen has R/r 26/11 mm, 13 superomarginals, and 12 cribriform organs. Five larger specimens have R/r 54/21, 55/19, 60/21, 61/21, and 70/21 mm, 17, 19, 19, 22, and 22 superomarginals, and 12-13, 12, 16, 14-15, and 14 cribriform organs respectively. The remaining seven specimens from st. 314 are also medium-sized ones with R about 60-70 mm, but very damaged.

The material of *Thoracaster* thus comprises both juvenile specimens (corresponding to PERRIER's *Pseudaster cordifer*) as well as specimens as large as or slightly larger than any hitherto on record. Specimens with R/r about 25/10 mm or more, show full-grown characters, and the largest specimens available show in part what must be considered senescent characters. The ratio R/r is hardly 2 in the smallest specimens, about 2.5 in the smaller ones with the full-grown characters, increases to about 3 in the medium-sized specimens with R 50-60 mm, and to almost 4 in a few of the largest specimens present.

The description of the specimen from st. 282 with R/r 87/23 mm (pl. V) is used as a starting point in the following survey of the present material and of its variation.

The superomarginals in the specimen with R/r 87/23 mm number 24-26 to each side of the mid-interradial unpaired plate, and join their opposites in the mid-dorsal line from about no. 7, the unpaired plate not included. In most of the other full-grown specimens, however, the superomarginals join from the eight opposite pair. In a few specimens they do not join until the ninth plates, and one of the largest specimens, with R/r 101/30 mm and 28 superomarginals, is distinguished by having these separate as far as to the tenth or eleventh opposite pairs. (This specimen has also unusually many cribriform organs). A juvenile specimen with R/r 13/7 mm has all the 6-7 paired superomarginal plates separate (fig. 10*a*). Another juvenile with R/r 14.5/7 mm has 8 superomarginals which join from no. 6 (fig. 10*k*). The superomarginals of either side of the arms are usually exactly opposite each other (fig. 10*p*), but may in rare cases subalternate (fig. 11*a*). The distal 2-3 superomarginals are rudimentary and situated below the terminal ossicle.



For the legend to the figure see opposite page.

The marginals bordering the disk are all subquadrate. In the arms the superomarginals are higher than long, distally up to twice as high as long.

The inferomarginals are proximally in the arms only slightly lower than their superomarginal companions, but decrease towards the arm end relatively more in height. Below the terminal ossicle there is often 1-2 inferomarginals more than superomarginals. The inferomarginal plates in general are arranged exactly corresponding with the superomarginal ones, but in some specimens they may subalternate with these for a varying length of the arms. LIEBERKIND (1932 p. 285) described a subalternation of the marginals in the Valdivia specimen, and noted that "Inwieweit es sich hier nur um eine individuelle Variation handelt, kann ich nicht mit Sicherheit bestimmen, da ja nur ein Exemplar vorliegt". In this connection it may be emphasized that the typical regular arrangement of the marginal plates has been found subject to individual variation in almost every population of porcellanasterids studied here, and especially, of course, in the long-armed forms.

The inferomarginals of the disk in the specimen with R/r 87/23 mm bear ventrally two small spines (distinctly larger than the ventrolateral spinelets) placed with one to each lower corner of the cribriform organs; and the proximal inferomarginals of the arms have a single similar small spine placed medially near the margin. All the marginal plates are further provided with a series of close-set minute spinelets along their margins (fig. 10*h*).

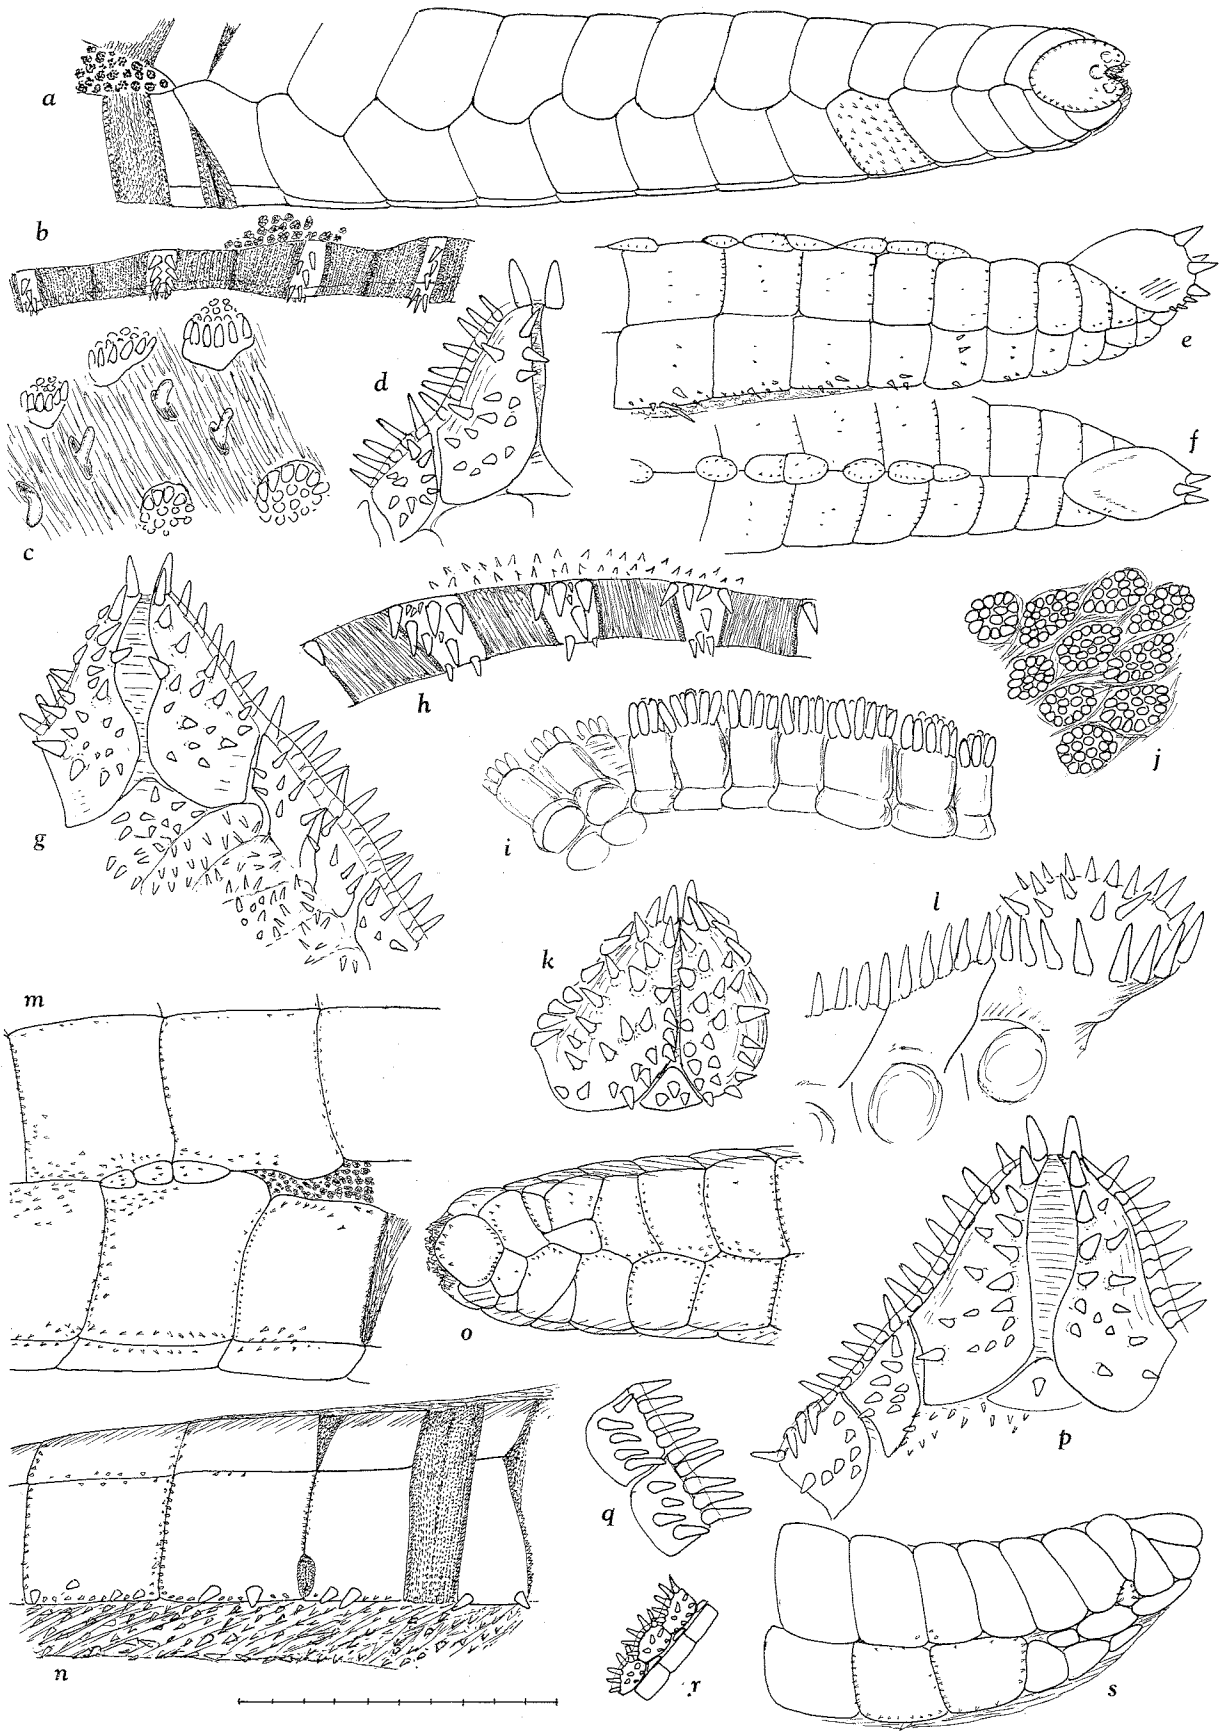
Some other specimens show an even more developed spine-armature on the marginals. Between the cribriform organs there may be one or two medial irregular rows of some small spines, and at the lower edge of the inferomarginals 3-4 small spines besides some spinelets, e. g. in the specimens from sts. 314 and 238, with R/r 54/21 and 89/28 mm respectively, as shown in fig. 11*b* and *h*. Minute spinelets may also be scattered over the surface of all the marginals, and sometimes even form a uniformly spaced covering (fig. 11*a*). The series of minute spinelets along the vertical sutures may appear rather like the fascioles in the astropectinids, or as rudimentary cribriform organs (figs. 10*w*, 11*n*).

The character which should distinguish KOEHLER's *T. alberti* from SLADEN's *T. cylindratus* was, as noted, an armature of minute spines between the cribriform organs. The most spiny specimens of the present material represent the form *T. alberti,* whereas a specimen as that with R/r 87/23 mm, with regard to the spine-armature represents a condition transitional to that of the type of *T. cylindratus,* with no spine-armature between the cribriform organs (to which condition there is but a slight step). The rather small specimens of *Thoracaster* collected by the Swedish Deep-Sea Expedition in the Atlantic had a few small spines along the ventral edge of the inferomarginals, the two at each side of the cribriform organs being the larger. Also specimens of LUDWIG's *T. magnus,* according to H. L. CLARK, have minute spines or spinelets at the ventral and dorsal margins of the marginal plates between the cribriform organs. (Such spinelets further may be easily rubbed off and lost). The conclusion can only be that it is impossible to upheld *T. alberti* as a distinct species.

Cribriform organs occur in the specimen with R/r 87/23 mm in a number of 14 fully developed ones in each interradius, and there may further be an additional rudimentary organ to either side of this series, and in some interradii thus up to 16 cribriform organs in all. The cribriform organs are of a papilliform structure. Each organ in the specimen with R/r 87/23 mm may comprise as many as 30 rows of papillae, and the median organs may join their neighbours at the dorsal edge of the superomarginals and almost meet also at the horizontal suture, whereas they narrow somewhat down towards the ventral edge of the inferomarginals.

A varying number of the median cribriform organs in the large specimens usually coalesce with their adjacent partners at the horizontal suture, leaving free only a ventral triangular area on the inferomarginals, with a few small spines, and a similar

Fig. 10. *Thoracaster cylindratus.* a-b) St. 281, R/r 13/7 mm. c) St. 281, R/r 20/10 mm. d) St. 281, R/r 41/12 mm. e-f) St. 280, R/r 86/24 mm, two different arms. g-h) St. 282, R/r 87/23 mm, arm in lateral view and in dorsal view respectively. i-k) St. 314 R/r 15/7 mm; j, paxillae in four times the usual scale. l) St. 314, small specimen, base of arm in dorsal view. m-q) St. 299, R/r 31/11 mm; n, adambulacral ossicle no. 10; o, paxillae in four times the usual scale; q, odd marginals and first paired marginals (to the right). r-v) St. 314, R/r 26/11 mm; r, dorsal paxillae in four times the usual scale; v, paired inferomarginal plate no 1 in ventral view. w-x) St. 314, medium-sized specimen; w, arm in dorsal view and in lateral view, spine-armature indicated on some of the marginals; x, ventral view of same arm. y-å) St. 314, R/r 55/19 mm; y, odd inferomarginal plate and paired inferomarginals nos. 1-2 (to the right) in ventral view; z, part of disk with madreporite; æ, large and smaller paxillae in four times the usual scale; å, part of ventral side with the adambulacralia nos. 1-3.
Scale: 10 mm (in j, o, r, and æ 2.5 mm).



For the legend to the figure see opposite page.

triangular area dorsally on the superomarginals, or, if also coalesced dorsally, only a small patch centrally on each superomarginal plate. The rudimentary cribriform organs may be developed from the dorsal and the ventral edge of the marginals simultaneously.

The number of cribriform organs in a juvenile specimen with R/r 13/7 mm is still only 4-6 in each interradius, but others of about similar size have already 8-10 (12) such organs. All the specimens at hand with R/r about 25/10 mm or more, have at least 12 cribriform organs developed. The largest known specimens, with e. g. R/r 103/30 mm, may also have only 12 cribriform organs, but 14 to each interradius is most common, and is found also in specimens as small as with R/r 31/11 mm. Besides the specimen with R/r 87/23 mm, only a single other one, with R/r 60/21 mm, has 16 cribriform organs.

The extraordinarily high number of 24 cribriform organs in each interradius, is found in the specimen with R/r 101/30 mm, one of the largest available and that with the largest disk, i. e. largest number of interbrachial marginals, its superomarginals not meeting in the arms until nos. 10-11. (Pl. VI 7). The series of cribriform organs in this specimen consists of 18 fully developed organs (with up to about 30 rows of papillae) and to either side of these 2 rudimentary ones. Sixteen of the organs are coalesced at the horizontal suture, and the median ones also ventrally and dorsally, so that the marginals have only a small central patch free. The rudimentary outermost organs reach from the ventral margin of the inferomarginals half-way up on the superomarginals, or only to the horizontal suture.

In the specimen with R/r 87/23 mm, a varying number of small rounded plates is found in the midline of the arms, inserted between the two rows of otherwise joining superomarginals. They occur in a continuous series for a distance of eight pairs of superomarginals in the proximal half of one arm, but in another arm they are only present between the first three pairs of superomarginals. They may also be found scatteredly far out in the arms, though never between the last few pairs of joining plates.

Both large specimens from st. 280, with R/r 84/22 and 86/24 mm, show arms without a single supplementary dorsal plate, besides an arm in which there is a continuous series of small dorsal plates, reaching almost to the terminal ossicle. Also small specimens, e. g. one with R/r 20/10 mm, may have a continuous series of small dorsal plates for almost the whole arm length (fig. 10*c*). This character thus is not one of age. Secondary dorsal plates occur in most specimens only in the proximal part of the arms.

The presence of such a series of supplementary dorsal plates in the arms was, as mentioned above, considered the character distinguishing *T. magnus* from *T. cylindratus*. That it is of no taxonomical value, however, is evident from the variation met with in the present material.

The terminal ossicles in the specimen with R/r 87/23 mm are small but fairly conspicuous since they, so to speak, ride on the arm ends, covering the outermost two or three pairs of rudimentary superomarginals. One has 3 small conical spines preserved on its distal end around the end of the furrow (fig. 10*h*), whereas the others appear naked. Along their proximal margin the terminal ossicles bear a row of minute spinelets like those on the marginal plates, and minute spinelets may also occur on their main surface. Seen from the side the terminal ossicles are high, subcircular, seen from above they show an oval contour.

This appearance of the terminal ossicles is the usual for medium-sized specimens, but the number of spines around the furrow end may be larger. There may be two additional pairs of subequal subterminal spines and further a few spinelets to each ventral side of the ossicle (or in other words up to 5 pairs of subterminal spines or spinelets). Possibly there may also be a few spinelets distally on the lateral sides, and occasionally there may also be an additional unpaired dorsal spine, close to the terminal one. In these medium-sized specimens the terminal ossicles are of about the same width as the arm-ends. In the large specimens the terminal ossicles become relatively smaller in relation to the arm ends which increases in thickness with age so that the terminal ossicle in a large specimen may be only

Fig. 11. *Thoracaster cylindratus*. a-d) St. 314, R/r 54/21 mm; b, arm angle in dorsal view, the odd superomarginal plate is the second from the left; c, paxillae and papulae in four times the usual scale. e-h) St. 238, R/r 89/28 mm; e-f, same arm in lateral view and in dorsal view; h, inferomarginals nos. 1-3 in ventral view. i-o) St. 238 R/r 100/27 mm; i-j, two groups of paxillae in lateral and dorsal view respectively; k, jaw in ventral view; l, another jaw in lateral view; m, arm base in dorsal view, showing the superomarginals nos. 7-9; n, same in lateral view; o, distal end of same arm. p-r) St. 232, R/r 101/30 mm; q, adambulacralia nos. 10-11; r, adambulacralia nos. 33-35. s) St. 238, R/r 103/30 mm, distal end of arm.
Scale: 10 mm (in c, i and j: 2.5 mm).

half as broad as the end of the arm, and when seen from the side, often almost hidden by the superomarginals, which have grown up around it.

This excessive development of the distal superomarginal plates probably is a consequence of senescence, the growth of the arms in length by the interpolation of new superomarginal plates at the terminal ossicle having stopped. A size of R/r about 100/30 mm then may be about the maximum-size attained by the species. In the large specimens the terminal spines also often seem to disappear. In the juvenile specimens the terminal ossicles are wider than the arm ends, broader than long, and with a concave proximal margin. With increasing age the terminal ossicles grow longer, their proximal border becoming straight in specimens with R about 15-20 mm, and the ossicle having its final appearance in specimens with R about 25 mm.

The whole dorsal area of the disk is covered with close-set paxillae (figs. 10*j, r;* 11*i-j*). In the specimen with R/r 87/23 mm the paxillae are mainly oval in outline in radial direction and bear on the average 12 spinelets (18 being the largest number of spinelets counted). Centrally on the disk the specimen shows an apical cone with smaller paxillae with only 2-3-4 spinelets.

In the juvenile specimens available, the number of spinelets to each paxilla is 2-3-4 in one with R/r 13/7 mm, and about 4-6 and up to 10, respectively, in two other specimens of the same size. The largest number of spinelets to a paxilla is about 12 in some specimens with R/r ranging from about 25/10 to 42/12 mm, but about 15 in some others of the same size. Specimens ranging from R/r 66/23 mm to the largest ones on record, may have about 20 spinelets to a paxilla as the largest number. The large specimen from st. 232 with R/r 101/30 mm thus has mainly 12-16 spinelets to each paxilla, and 21 as the largest number counted. Other specimens with R/r 60/20 to 86/24 mm have paxillae with up to 25 spinelets, and still others with R/r 54/21 mm or more, have paxillae with up to about 30 spinelets. As many as 33 spinelets were counted on a paxilla of a specimen with R/r 70/24 mm.

All paxillae in the same specimen are subequal in height. The shafts in the smaller paxillae are therefore higher than wide, whereas in the larger ones they are about as wide as high. Very often the paxillae are suboval in outline and in general they are arranged with their larger diameter in radial direction.

The juvenile specimens are provided with a distinct, though short apical appendage, and an apical appendage may also be found in specimens as large as with R/r 31/11 mm. Larger specimens may show a more or less distinct apical cone, e.g. the two specimens from st. 280 with R 84 and 86 mm. Also the one from st. 232 with R/r 101/30 mm show a faint apical cone. Usually, however, the large specimens have no apical cone formed, having the central area of the disk marked off only by a number of small paxillae, i. e. with a crown of only a few spinelets and a slender shaft, but in height subequal to the other paxillae of the disk.

Papulae were only discernible in a few specimens which were especially well expanded. In one of the largest specimens they were found extending into the arm bases to either side of a 3-4 paxillae broad area radially.

The madreporic body has the striae stretching across in radial direction or radiating from an adcentral point. In the large specimens it is fairly inconspicuous, of a diameter about equal to the length of the adjoining marginals or somewhat less, and separated from these by a few rows of paxillae.

The adambulacral ossicles number 38 in the specimen with R/r 87/23 mm. The proximal ones carry in general 4-5 subequal furrow spines, but 6 furrow spines may be found on some ossicles, also among the distal ones. The proximal adambulacralia are subrhomboid in contour, but from about the sixth ossicle their shape changes, and they gradually become more narrow, especially their distal end narrowing down to give room for the podia. In the arms the interradial margin of the adambulacralia becomes curved, and the ends of the ambulacral ossicles are exposed. The furrow spines are subequal, and on the proximal adambulacralia arranged in a continuous series, whereas on the more distal ones the aboral furrow spine becomes placed on the narrow part of the ossicle at a small distance from the other 3-4 ones on the adoral half or two-thirds of the margin.

The furrow spines appear rather slender conical or spindle-shaped, though more or less flattened in vertical direction and with a short and somehat broader basal part marked off by a faint constriction. This basal part is imbedded in the strong web which connects the whole series of adambulacral and oral spines (figs. 10*m, t,* and 11*g, p*).

On their surface the adambulacralia in the specimen with R/r 87/23 mm are provided with a number of subambulacral spinelets; on one of the proximal ossicles e. g. 7 arranged in two irregular longi-

tudinal series. The subambulacral spinelets are subequal on the proximal ambulacralia, but from about the sixth ossicle, the most aboral one becomes larger than the others, reaching the same size as the furrow spines. Of the other 4-8 subambulacral spinelets, two are generally placed at the adoral margin of the ossicle and the others in an irregular longitudinal series between these and the large aboral spinelet.

A number of 4 or 5 adambulacral spines appear to be equally frequent in the specimens available, also in the juveniles. The specimen with R/r 13/7 mm has 3 furrow spines on some of the ossicles in the arms, but otherwise the number is 4. A few specimens, also some small ones, have 6 furrow spines on some ossicles. One of the largest specimens, R/r 100/27 mm, has 5 furrow spines as the most common number, but on some ossicles it has 6, and on the proximal ones occasionally even 7 furrow spines.

The number of adambulacral ossicles is 11 in a specimen with R/r 13/7 mm and 6 paired superomarginals, 14 in one with R/r 14.5/7 mm and 8 superomarginals, 21 in one with R/r 26/11 mm and 12 superomarginals, 22 in one with R/r 31/11 mm and 14 superomarginals, and 40 in one with R/r 101/30 mm and 28 superomarginals.

The oral ossicles are fairly inconspicuous since their surface is more or less level with that of the ventrolateral area, and since the suboral armature of spines fairly gradually pass into the ventrolateral spine armature. In the specimen with R/r 87/23 mm the oralia carry marginally 8 spiniform spines, the proximal one slightly larger than the others, which are subequal in size. On their surface the oralia are provided with about 20 fairly uniformly spaced spines, thus along the sutural edge a series of about 8 which gradually decrease in length from the proximal to the distal one, the proximal spine in the series being close to and of about the same size as the enlarged proximal oral spine; on the main surface up to 6 spines, the largest of which are subequal to the marginal spines, and further some few additional suboral spines or spinelets near the distal margin.

The oral armature of the medium-sized and larger specimens agree with the above description (cf. eg. fig. 11 *d, g*). The number of suboral spines increases with age, whereas the number of marginal oral spines is about the same in the smallest as well as in the largest specimens available. In a juvenile specimen with R/r 13/7 mm the usual number of marginal oral spines is 6, but 7 occur on some ossicles. Another juvenile specimen with R/r 15/7 mm has 7-8 marginal oral spines. The larger specimens, inclusive of the largest present, generally have 7 or 8 marginal oral spines, but a few large specimens have a marginal series of 9 spines on some oralia, and also a specimen with R/r 60/21 mm has 8-9 such spines. The proximal oral spine usually is about twice as large as the others, but sometimes it is only slightly larger. In the juvenile specimen with R/r 13/7 mm there may be only 4 suboral spines; in the specimen with R/r 14.5/7 mm there are 5-6, and in one with R/r 26/11 mm 6-7 suboral spines. A specimen with R/r 89/28 mm has 16-20 suboral spines, and the largest specimens with R about 100 mm (fig. 11 *p*) have about 15 to 24 suboral spines and spinelets on each ossicle.

The primary oral ossicle is not very conspicuous. It has a naked surface in the specimen with R/r 87/23 mm, but in other specimens it is often armed with one or a few spinelets similar to the small suboral ones and to those of the ventrolateral area.

The ventrolateral area is closely paved with overlapping small plates (their adoral border free). The specimen with R/r 87/23 mm has 3-4 ventrolateral plates in the first tangential row at the oralia, and each of these plates carry up to about ten slender spinelets, distributed all over the surface of the plates though mainly along their proximal border. The median ventrolateral plates carry about 4 spinelets, all placed at the adoral edge, and the most distal and smallest plates, 8 of which about correspond with a marginal plate, carry only a single spinelet each. Small ventrolateral plates occur in the present specimen out in the arms to the inferomarginals nos. 20-22.

A radiating arrangement of the slightly transversely elongate or subhexagonal ventrolateral plates may be rather distinct in the juvenile specimens. In the large specimens these plates become so crowded however, that only the tangential and longitudinal arrangements are perceptible. The ventrolateral plates in the large specimens are further concealed by a fairly thick integument. Often there are only two ventrolateral plates in the first tangential row, and each of these plates may carry up to 15 spinelets in the largest specimens. About 8 ventrolateral plates, with single spinelets, correspond also in the largest specimens with a marginal plate. Generally the ventrolateral plates extend almost to the end of the arms, in the large specimens in several series. In the specimen with R 100 mm and 26 in-

feromarginals, ventrolateral plates thus are present to the 18th or 19th inferomarginals.

Distribution:

Thoracaster cylindratus is hitherto known from 19 dredgings in depths ranging from 2600 to 4990 m (11 of them in depths exceeding 4000 m). Six of the dredgings were in the eastern and tropical Atlantic, eight in the northern Indian Ocean, and five in the eastern tropical Pacific. (Fig. 33). Specimens of *Thoracaster* are further collected by the Vitjaz in the western North Pacific (Kurile-Kamchatka Trench) in about 4000-5000 m. *Thoracaster cylindratus* has been found on a bottom of globigerina ooze, calcareous clay, and white, grey, yellowbrown, green, or black mud, at temperatures between 1.3° and 2.8°C.

Styracaster Sladen, 1883

Type-species: *Styracaster horridus* Sladen, 1883.

Syn.: *Machairaster* E. Perrier, 1884 (type-species: *Machairaster pictus* E. Perrier, 1884 = *Styracaster spinosus* E. Perrier, 1885).

Chunaster Ludwig, 1907 (type-species: *Chunaster scapanephorus* Ludwig, 1907 = *Styracaster horridus* Sladen).

Diagnosis:

Porcellanasterids with superomarginals forming a complete casing to arms. A varying number of erect spines in arm midline. Superomarginals of disk unarmed. A mid-interradial suture. Cribriform organs (3-11) confined to marginals of disk.

Description:

The disk is pentagonal. The arms are well set off, narrow, tapering and more or less compressed. Their length varies considerably in the different species. R is known to reach a length of almost 150 mm in some species; and in some large specimens the ratio R/r may exceed 6. In one species, however, the ratio R/r may be less than 2 even in adult specimens. The body is flat when the stomach is empty, and neither is it very tumid when the stomach is full. The terminal ossicle is fairly conspicuous and rather distal to the arm end. The whole dorsal side may be uniformly covered with well developed paxillae, but in some species there is a pavement of naked plates at the arm bases, and in others there are no paxillae at all, but only spiniferous plates. The jaws show a prominent keel formed by the interradial part of the two combined oralia, which are separated by a suture of varying width, meeting proximally and usually also medially, but this latter not in all species. The primary oral ossicle has a triangular surface well exposed. The oralia carry a varying number of marginal spines, the proximal of which is the largest. The elongate adambulacralia of the main part of the arms show a protruding adoral part with a varying number of furrow spines, and an incurved aboral part, either naked or with a single isolated furrow spine. The ventrolateral area has a pavement of plates, naked or with scattered granules. The surface of the oralia, and the adambulacralia, may likewise be either naked or provided with a small number of granules or spinelets.

Remarks:

SLADEN (1883) erected *Styracaster* to comprise his two species *horridus* and *armatus,* and several other species have later been ascribed to the same genus, viz. *spinosus* and *edwardsi,* by E. PERRIER in 1885, *clavipes* by WOOD-MASON & ALCOCK in 1891, *chuni, caroli, monacanthus,* and *paucispinus,* by LUDWIG in 1907, and *elongatus,* and *robustus,* by KOEHLER in 1907 (*a* and *b*). Further LIEBERKIND in 1935 described a new subspecies: *chuni* var. *groenlandica.* The specimen mentioned as *Styracaster* sp. by CHUN in 1900, was by LUDWIG in 1907 described as representing a new genus and species, *Chunaster scapanephorus,* which, however, is identical with SLADEN's *Styracaster horridus.* The form which E. PERRIER in 1884 referred to as *Machairaster pictus* is the same as he later called *Styracaster spinosus.*

A total of 12 species has thus been described in the genus *Styracaster* (inclusive of *Chunaster*), and presumably most of them are valid. The Galathea Expedition collected 54 specimens of *Styracaster* in all, representing 5 different species, all previously described; and this fairly large material has made it possible to undertake a comparative study of the species of the genus, and to form an idea of the infraspecific variation, and also to evaluate the characters distinguishing the different species.

Juvenile specimens of *Styracaster,* in *S. horridus* e. g. up to a size of R about 30 mm, have still only poorly developed dorsal paxillae even if the adult specimens have dorsal paxillae crowned with a large number of spinelets. The present author in 1951 ventured, therefore, to set forth the opinion that some of the species of *Styracaster* described as being without real paxillae, would prove to be based on

juvenile specimens, and the character of their dorsal armature thus be of no taxonomical value. The present study has, however, disproved this supposition. A specimen of *S. armatus* in the Galathea material clearly shows that SLADEN based his description of this species on an adult specimen. The type-specimens of E. PERRIER's *S. spinosus* and *S. edwardsi* were small, considering the size attained by such species as e. g. *S. horridus* and *S. elongatus,* but later material of *S. spinosus* has shown that pseudo-paxillae with only single spinelets are found also in the full-grown specimens. (Incidentally, *S. spinosus* and *S. edwardsi* are almost certainly synonymous).

The species of *Styracaster* (some of them perhaps only nominal) may be grouped as follows:

1) A group symbolized by the type-species *S. horridus* (of which *Chunc ster scapanephorus* is a synonym), and further comprising *S. caroli* and also *S. elongatus*. These three species are well distinguished.

2) A group symbolized by *S. chuni,* and comprising also *S. paucispinus,* and further *S. robustus.*

3) A group symbolized by *S. armatus* and comprising also *S. spinosus* (with which *S. edwardsi* is almost certainly identical), and the uncertain *S. clavipes* (perhaps also identical with *S. spinosus*). – The taxonomical status of the forms in this group thus is not yet quite clear.

Finally *S. monacanthus* may be ranged in a group of its own, but apparently near that of *S. armatus.*

Nec: *S. horridus,* RICHARD 1903, = *S. elongatus* Koehler, 1907.

The type-specimen of *Styracaster horridus* was collected by the Challenger in the tropical eastern Atlantic (st. 346: 2°42'S, 14°41'W, 4298 m, globigerina ooze, 1.1° C.), and it appears from SLADEN's text that at least one other larger specimen was at disposal. (WYVILLE THOMSON (1877 pt. II p. 267) noted from the haul "three fine specimens of a new species of *Porcellanaster* remarkable for a series of long spines running along the centre of the back of each ray".)

The type-specimen has R/r 75/15 mm; 23 superomarginals, all longer than high, and according to the figure joining their opposites from plates no. 4. A continuous series of erect slender sharply pointed spines along midline of the laterally compressed arms, borne generally on alternate plates of all successive pairs of opposite superomarginals. Proximal arm spines longer than height of arms, towards arm tips decreasing fairly regularly in lenght. Inferomarginals about twice as long as high. 7-9 papilliform cribriform organs. Terminal ossicle rather compressed, elongate in contour (dorsal to about two rudimentary superomarginals), with 3 spines, a terminal one and a pair of subterminal ones (in a large specimen possibly with an additional spine in the dorsal midline). Dorsal side of disk with closely crowded small pseudo-paxillae with 4-8 spinelets. Adambulacralia elongate, subrhomboid, with furrow margin and ventral side incurved, proximal ossicles with 5 subequal short flat and pointed furrow spines, those of arms with 3 short slightly compressed and sharply pointed spines on adoral part of furrow margin, and a much longer and pointed spine on aboral part. (In large specimens 1-3 adorally placed subambulacral granules). Oralia with a pointed conical spine on tip (or two such spines, one above the other), and a series of 7-8 subequal short and flat spines along lateral margin. (In a large specimen 4-5 suboral granules in a series along median suture). Ventrolateral area with transversely elongate plates with spaced irregularly placed granules.

KOEHLER in 1909 records two specimens of *Styracaster horridus* dredged by the Princesse Alice in the Bay of Biscay and east of the Azores respectively (st. 757: 44°06'N, 10°22'W, 4900 m, muddy ooze; and st. 1789: 31°06'N, 24°00'W, 5413 m). R/r are ?/22 and 34/9 mm. The smaller specimen has 15 superomarginals, 5 cribriform organs, only few arm-spines, and in most cases only 3 adambulacral spines.

In 1921 KOEHLER records three additional specimens from three other dredgings of the Princesse Alice, all in the Bay of Biscay (st. 2986: 45°08'N, 7°06'W, 4870 m; st. 2994: 44°08'N, 10°44'W, 5000 m; and st. 2997: 44°29'N, 10°31'W, 4965 m).

Finally the present author, in 1951, described three juvenile specimens of *Styracaster horridus* from a dredging made by the Swedish Deep-Sea Expedition in the tropical Atlantic near the type-locality (st. 329: about 9°44'N, 26°25'W, 5610-5600 m, calcareous red clay, 2.4° C.). The specimens in question had R/r 30/8, 23/7, and 13/5 mm, and 15-17, 13-15, and 11 superomarginals respectively. The largest one agreed fairly well with the type, whereas the two smaller ones were still without paxillar spinelets and had only a few arm-spines (one of these always on the first pair of joining superomarginals).

Styracaster horridus was also recorded from the Indian Ocean by WOOD-MASON & ALCOCK (1891), but according to KOEHLER (1909*a*), who has re-examined these author's material, the specimens in question actually belonged to *Styracaster caroli*.

Chunaster scapanephorus: This genus and species was briefly diagnosed by LUDWIG in 1907 on the basis of a specimen collected by the Valdivia Expedition in the Indian Ocean south of Sumatra (st. 183: 8°14'S, 98°22'E, 5248 m, radiolarian ooze), and previously (on basis of LUDWIG's preliminary identification of it) listed as *Styracaster* sp. by CHUN (1900), who also published a photograph of it. The same specimen was subsequently given a more detailed and fully illustrated description by LIEBERKIND in 1932.

The type-specimen of *Chunaster scapanephorus* has R/r 98/27 mm; 24-30 superomarginals, longer than high, joining their opposites from plates no. 6. Along the midline of the laterally compressed arms a series of 11-14 erect slender pointed spines, one to each pair of joining superomarginals, proximally at least as long as the arm is high, more or less regularly decreasing in length towards the arm ends. Inferomarginals of disk subrectangular, of arms four times as long as high; 11 cribriform organs. Terminal ossicle laterally compressed, with 3 spines. Whole dorsal side with close-set paxillae with 4 (-6) spinelets. Adambulacralia of arms elongate, with an incurved furrow margin, adorally with a series of (3-) 5 spatulate furrow-spines in a common web, and aborally with a larger conical pointed spine. Proximal 3-4 adambulacralia relatively shorter, with a continuous series of 9-10 spatulate furrow spines, and further with up to about 5 subambulacral granules

on adoral surface. Oralia each with a stout conical spine at tip, and laterally with a series of 9 (-10) spatulate marginal spines similar to adambulacral ones; also a suboral granule. Ventrolateral area paved with proximally spaced, and distally closeset and in radial series arranged plates with scattered granules. Minute ventrolateral plates extending in about a double series almost to terminal ossicle.

If this description is compared point by point with that of the type-specimen of *Styracaster horridus,* it appears that the only character by which *Chunaster scapanephorus* is distinguished is in the presence of ventrolateral plates in the arms, almost to the arm end. The larger number of cribriform organs in *Chunaster scapanephorus* is accounted for by the larger size of this specimen, and the peculiar adambulacral armature, which LUDWIG and LIEBERKIND emphasize as especially characteristic of the form, really is exactly identical (and also identically described) in *Styracaster horridus.*

The Swedish Deep-Sea Expedition collected in the tropical mid-Atlantic, (st. 342: about 1°N, 18°40'W, 5250-5300 m, globigerina ooze, 2.3°C.) quite near the type-locality of *Styracaster horridus*, six porcellanasterids which the present author in 1951 recorded under the name of *Chunaster scapanephorus,* since they had a series of ventrolateral plates in the arms and also in all other characters agreed well with the description of this form given by LUDWIG and by LIEBERKIND. They had R/r ?/11, 52/12, 52/14, 51-55/16, ?/17 and 58/17 mm; about 18-19 superomarginals, joining from nos. 5-6; and 10-14 arm spines. Terminal ossicles sometimes with a fourth spine in the dorsal midline. (See fig. 13*f-i*).

Since these two named forms, *Styracaster horridus* and *Chunaster scapanephorus,* differ between themselves merely in the extent to which a ventrolateral armature of plates is developed in the arms, whereas in several of their other common characters they differ markedly from the other species described of *Styracaster,* they cannot possibly be generically different. Now, the possession of ventrolateral plates in the arms might be a character of specific or subspecific importance. But the material from the Galathea Expedition to be described below shows a so diverse armature of ventrolateral plates in the arms that it cannot be considered of any taxonomic importance specifically; no more than could e. g. the armature of secondary dorsal arm plates in *Thoracaster.*

The Galathea material:

A total of 24 specimens and some fragments of *Styracaster horridus* were dredged at seven stations: in the Atlantic in the Gulf of Guinea, in the Indian Ocean off Tanganyika and south of Ceylon, and in the South Pacific in the Kermadec Trench north of New Zealand, respectively.

St. 30: 0°42'N, 5°59'W, 5160 m, 2.2°C., clay. 10 specimens.
St. 234: 5°25'S, 47°09'E, 4820 m, 1.8°C. 3 specimens.
St. 235: 4°47'S, 46°19'E, 4810 m, 1.4°C., globigerina ooze. 1 specimen.
St. 282: 5°32'N, 78°41'E, 4040 m, 1.5°C., blackish mud. 2 specimens.
St. 663: 36°31'S, 178°38'W, 4410 m, 1.2°C., brown, sandy clay. 2 specimens.
St. 664: 36°34'S, 178°57'W, 4540 m, 1.1°C., brown, sandy clay. 6 specimens + fragment.

All the specimens available from the Atlantic and the Indian Ocean have the characteristic adambulacral armature described for the types of *Styracaster horridus* and *Chunaster scapanephorus.* The material of two specimens from st. 282, south of Ceylon, agrees with the type of *Styracaster horridus* in the absence of a ventrolateral skeleton in the arms, whereas the other material, from off tropical West Africa and off tropical East Africa respectively, in every population includes specimens corresponding closely to the one described as *Chunaster scapanephorus,* in having ventrolateral plates extending into the arms. It has been found most convenient, therefore, to describe the specimens from st. 282 separately. Also the specimens from the two dredgings in the Kermadec Trench in the South Pacific, will be dealt with separately, since they differ somewhat from the other specimens by having a more simple adambulacral armature.

The specimens from st. 282:

The two specimens representing the population of *Styracaster horridus* found in this locality, south of Ceylon, have R/r 91/21 and 85/15 mm respectively. The larger one in general appearance agrees well with the type-specimen of *S. horridus,* having the arms armed with 11-13 dorsal spines, whereas the smaller one shows a very different appearance, as it has only a single dorsal spine on each arm (always belonging to the first pair of joining superomarginals). This specimen thus does not at all cor-

respond to the name of *horridus*. The specific identity of the two specimens, however, is beyond doubt, and, as will appear from the following, such an occurrence of one-spined specimens in a population of otherwise many-spined ones is known e. g. also in the species *Styracaster chuni*.

The specimen with R/r 91/21 mm (fig. 12*a-e, g-j, m*) has 30 superomarginal plates, which join from the fifth opposite pair. All marginal plates have a rather granulated surface. The superomarginal ones, of the arms as well as of the disk, are slightly longer than high, subrectangular if corresponding with their opposites and with the inferomarginals, but varying in shape to hexagonal if alternatingly arranged, which is a fairly frequent feature. Centrally the marginals show a faint depression.

The inferomarginal plates are in the arm angles about as high as the accompanying superomarginals, but proximally in the arms they are only about half as high, and distally only from one-third to one-fourth as high. In general they are of the same length as the corresponding superomarginals, but they may be shorter, so that e. g. 8 inferomarginals correspond to 5 superomarginals. In places the series of inferomarginals is interrupted by one or a few enlarged superomarginals reaching down to the ventral side.

The only two intact arms carry 11 and 13 dorsal spines respectively. The ten distal pairs of superomarginals are unarmed in both arms, and in one arm also the second, fifth, eight, and eleventh pair of joining superomarginals are without dorsal spines, whereas in the other arm it is the second, fourth, eighth and twelfth pair which are unarmed. The spine armature of these two arms is thus less developed than was the case in the type-specimen described by SLADEN. However, another, broken arm of the same specimen has a continuous row of dorsal spines on all the nine joining pairs of superomarginals left. In four of the radii in the present specimen there is another variation from the type-specimen, viz. that the most proximal arm spine (about 10 mm long) is developed already on the fourth superomarginal plate, which is completely separated from its opposite, whereas in the type (and in all other specimens described) the most proximal arm spine is always found on one of the plates of the first joining pair of superomarginals. The spines of the main (distal) part of the arms are slightly curved, with the point turned outwards, as was also noted by SLADEN for the type-specimen. They decrease more or less regularly in length as they proceed along the arm. (Fig. 12*e*).

The cribriform organs number 9 in each interradius in this specimen with R/r 91/21 mm. Each of the seven median ones, which consist of about 20-24 rows of papillae, covers a little more than one-third of each of the two sets of marginals on which they are developed. The series of covering papillae extends from one dorsal corner of the organ in a straight line almost to the ventral edge of the inferomarginal plate where it bends and continues near the margin and round to the other side of the organ, ending at the other dorsal corner. The outer cribriform organs, at the base of the arms, also reach almost to the ventral margin of the inferomarginals, from which they are demarcated by the series of covering papillae in the same way as are the median organs, but they do not reach to the dorsal side of the superomarginals.

The terminal ossicles have borne a fairly large spine at their tip, and further there is a pair of small subterminal spines. (Fig. 12*h*).

The whole dorsal area of the disk, inclusive of the arm bases, is covered with paxillae (fig. 12*m*), which usually are crowned by 6-7 spinelets, but sometimes have 8 or only 3-4 spinelets. This specimen with R/r 91/21 mm has the stomach filled to the utmost, and the whole disk area in consequence is much expanded, and the paxillae of the main part of the disk hence fairly spaced. (SLADEN's description of the shape of the disk in the type-specimen of *horridus* as not high, and the under surface convex, is of course an individual and not a specific characteristic). There is no apical cone. The dorsal integument is fairly thick and leathery, as noted by SLADEN. Papulae were not observed even though the specimen is well expanded.

The adambulacral ossicles number 45. Their armature consists on the proximal two to four ossicles (fig. 12*b, c*) of a furrow series with 4-5 blunt flat or spoon-shaped spines which as segmental papillae cover an oblong segmental pit, and further there are on the adoral part of the surface 2 or 3, sometimes 4 subambulacral granules. In the following adambulacral ossicles (fig. 12*d*) the aboral part narrows somewhat down to give room for the podia, and the furrow spines become pointed, and especially the distal one increases in length. The adambulacral armature in the arms (fig. 12*g, i, j*) then consists of a series of 3 (occasionally 4, and most distally only 2) flat and pointed spines on the adoral broad part of the ossicle, covering as segmental pa-

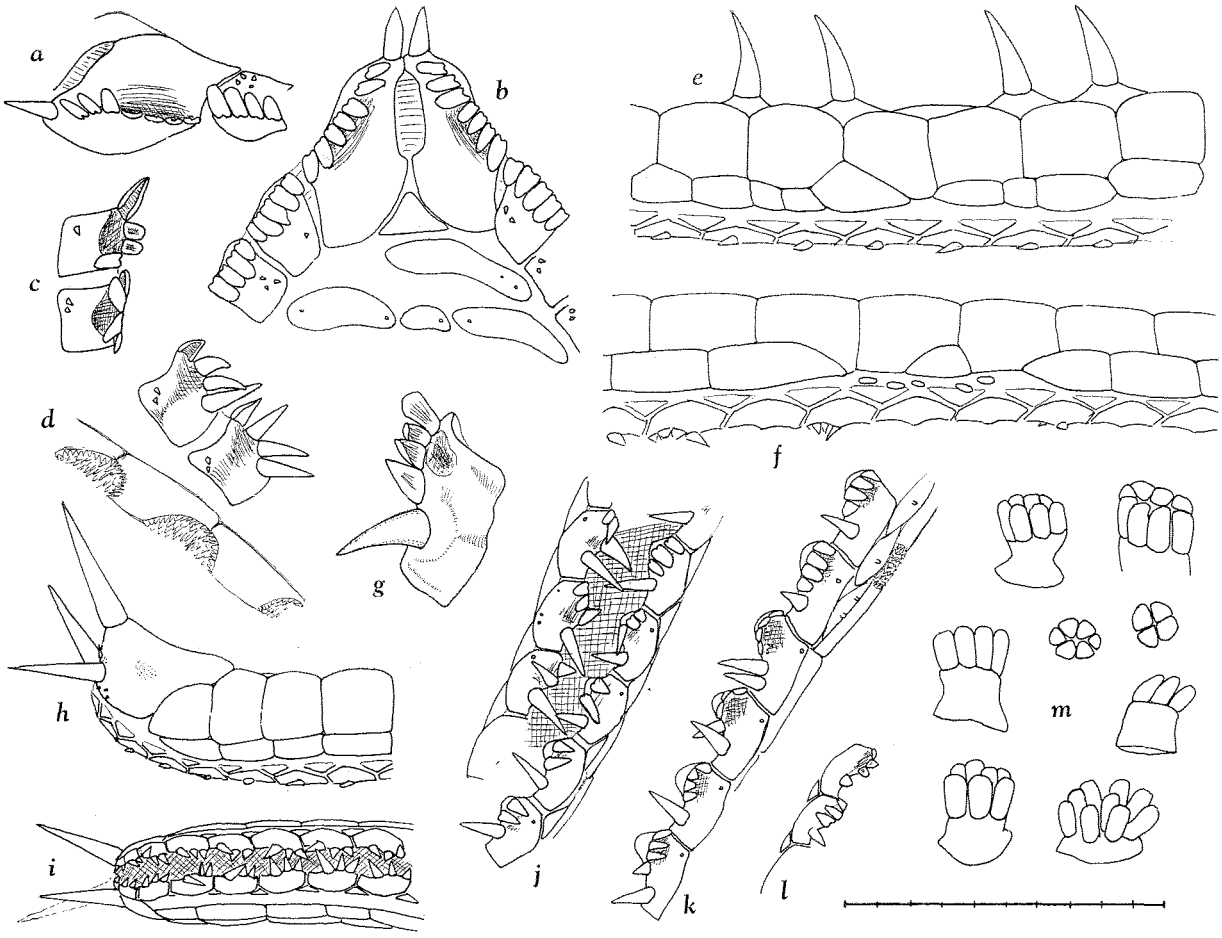

Fig. 12. *Styracaster horridus,* st. 282. a-e) R/r 91/21 mm (see also g-j and m); a, oral ossicle and first adambulacral ossicle in lateral view; b, another jaw in ventral view; c, adambulacralia nos. 3-4; d, adambulacralia nos. 6-7 and adjoining inferomarginals; e, part of arm, showing the superomarginals nos. 15-20, aboral end to the left. f) R/r 85/15 mm (see also k-l), part of arm, showing the superomarginals nos. 11-15, aboral end to the right. g-j) R/r 91/21 mm; g, adambulacral ossicle no. 15, seen obliquely from the side, in twice the usual scale; h-i, distal end of arm in lateral view and in ventral view; j, part of arm in ventral view, showing the adambulacralia nos. 22-26. k-l) R/r 85/15 mm; k, adambulacralia nos. 7-12; l, adambulacralia nos. 24-25. m) R/r 91/21 mm, paxillae in four times the usual scale.
Scale: 10 mm (in g: 5 mm, in m: 2.5 mm).

pillae a faint segmental pit, and of a spiniform pointed spine about as long as the ossicle, standing alone on the aboral narrow part at some distance from the adoral series. The more distal adambulacral ossicles carry further (always?) a single subambulacral granule near their outer adoral corner. The triangular ends of the ambulacral ossicles are distinctly visible in the arms (fig. 12*j*).

The prominent oral ossicles (fig. 12*a, b*) each carries a fairly large conical spine at the tip and along the margin a series of 8 about one-third as large, blunt and flat or spoon-shaped spines, which are to be described as a series of segmental papillae, and which cover a distinct, long segmental pit. The surface of the oralia is naked.

The ventrolateral plates are transversely elongate, arranged in about 6-8 tangential series, and distally also in radiating series, which two and two approximately correspond with an adjoining marginal plate. The proximal ventrolateral plates are about twice as large as the distal ones and more irregular, often rather boomerang-shaped with one part parallel to the furrow. The plates, especially the proximal ones, are fairly spaced, partly because the specimen is well expanded by a full stomach. They are covered with a fairly thick integument and each may carry up to half a dozen very minute granules. The ventrolateral plates are confined to the disk area. Only a narrow strip of naked skin extends between the series of inferomarginals and adambulacral ossicles.

The other specimen of *Styracaster horridus* from st. 282 (fig. 12*f, k, l;* pl. VIII 1-2) has R/r 85/15 mm

by an empty stomach. There are 25 superomarginals, joining their opposites from the fourth or fifth pair, and 8-9 cribriform organs, which in places coalesce with their neighbour to one or to either side. The specimen, as already mentioned, is remarkable in having only a single dorsal spine to each arm (always placed on one of the superomarginal plates of the first pair of joining ones). The specimen, however, is otherwise slightly more spiny than the other one. The terminal ossicle is provided with two pairs of small subterminal spines besides the large distal spine. There are 9 lateral oral spines besides the conical proximal one. The proximal three adambulacralia carry 5-6 spatulate furrow spines, and the vertebra-like adambulacralia of the arms (fig. 12*k*) carry an adoral series of 4 spatulate spines besides the longer spiniform spine aborally. A single plate was found with 2 aboral spiniform spines. A few subambulacral granules or granuliform spinelets occur in a transverse row near the adoral margin of the ossicles. The paxillae carry 4-8, mainly 6 spinelets. The madreporite, separated from the margin by a single row of paxillae, is round, with the striae radiating from an adcentral point, and along the adcentral edge provided with an armature of spinelets similar to those on the paxillae. There is a faint apical cone.

Nor in this specimen do the ventrolateral plates extend outside the disk area. In one arm, however, a few inferomarginal plates are missing at the superomarginals nos. 12-14, and the correspondingly broader strip of integument stretching between the series of marginals and adambulacral ossicles includes here a small number of spaced minute plates.

The specimens from sts. 30, 234, and 235. (Figs. 13-15. Pl. VII):

The ten specimens of *Styracaster horridus* from st. 30 have R/r in mm as follows (with the number of superomarginals added in parentheses): 15/6 (10), 20/8 (10-11), 35/9 (16-17), 58/12 (19), 60/13 (18), 63/15 (21), 66/19 (21), 68/14 (17-18), 75/16 (23), and 81/17 (23-25) respectively. The three specimens from st. 234 have R/r 45/14, 118-128/18 mm, and 118-131/20 mm, and about 23, 32, and 32-37 superomarginals; and the single one from st. 235 has R/r 118-146/29 mm by a full stomach (pl. VII) and 25-32 superomarginals. The ratio R/r increases thus from 2.5 in the smallest specimens with R about 15-20 mm to about 4 in specimens with R 35-81 mm, or to about 5, as in specimens with R 75 mm or more, thus also in the largest specimen with R 118-146 mm, even to 6.5 as in one with R 118-128 mm, which latter specimen, however, had an empty stomach and the disk area contracted so that the interradii are excave.

The superomarginal plates are in general subquadrate, slightly longer than high, but they may be distinctly rectangular. Those of either side of the arm may stand just opposite each other clear to the terminal ossicle, but they may also alternate more or less regularly, in which case they may be pentagular, even hexagonal if they alternate also with the inferomarginals. All kinds of arrangements may be found in the different arms of the same specimen. An irregular alternating arrangement seems the most common. The inferomarginal plates correspond in number to the superomarginals, proximally in the arms being about half as high as these and distally about one-third as high. Out in the arms the inferomarginals may alternate with the superomarginals, and then become subpentagonal instead of rectangular. The marginal plates have a granulated surface, and the superomarginals a fairly marked central depression.

The superomarginal plates join their opposites in the arms from plates nos. 4-5 in both small and large specimens, and from plates nos. 5-6 in the largest one with R 146 mm.

Dorsal arm spines are present in a number of 2 in the smallest specimen (fig. 13*a*), R/r 15/6 mm and 10 superomarginals, and in a number of 3-5 in the other small specimen, R/r 20/8 mm and 11-12 superomarginals. The specimen with R/r 35/10 mm has up to 8 spines to an arm, and one specimen with R/r 45/14 mm has 7 spines on the only arm preserved (with about 23 superomarginals). Some specimens with R about 60 mm have between 10 and 17 dorsal spines on each arm, and the same variation in number of arm spines is also found in some specimens with R about 70 mm. One specimen with R 75 mm has 17 spines on three of the arms, and 18 and 19 spines respectively on the two other arms. The two large specimens with R 118-131 mm, and 32 and 37 superomarginals, have 16-19 arm spines, whereas the largest specimen, with R up to 146 mm but only 32 superomarginals, have 10-11 arm spines.

The dorsal arm spines are often developed more or less regularly on every second superomarginal plate, alternatingly on either side of the arm (thus a spine for each successive pair of joining superomarginals), but they may also stand on successive plates on the same side for the greater length of

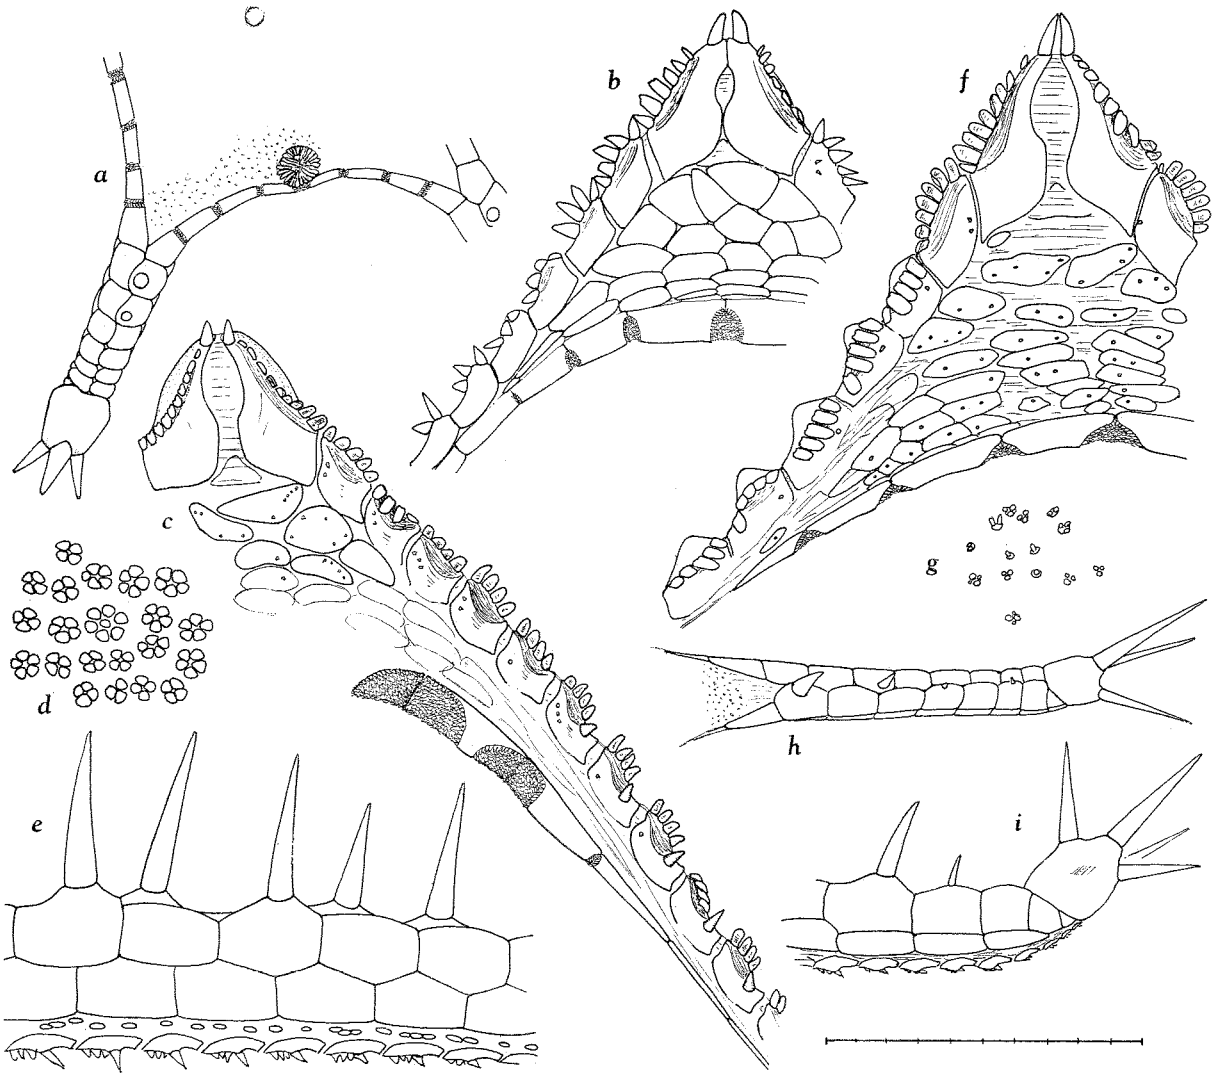

Fig. 13. *Styracaster horridus.* a-b) St. 30, R/r 15/6 mm; b, part of ventral side in twice the usual scale. c) St. 30, R/r 68/14 mm. d) St. 30, R/r ab. 65/15 mm, paxillae from midway between the center and the interradial margin of the disk, in four times the usual scale. e) St. 30, R/r 63/15 mm, part of arm in lateral view, showing the superomarginals nos. 7-11. f-h) Swedish Deep-Sea Expedition st. 329, R/r 24/7.5 mm; f, part of ventral side in twice the usual scale; g, paxillae in four times the usual scale. i) Swedish Deep-Sea Expedition st. 342, R/r 32/14 mm, distal end of arm.
Scale: 10 mm (in b and f: 5 mm. in d and g: 2.5 mm).

the arm, and, more rarely, they may be present on successive plates on both sides of the arm for some distance, thus being placed very closely. The largest spines are usually found a little out on the arms, on the ninth or tenth superomarginals, and thereafter they decrease fairly gradually in length towards the tip of the arms. The largest arm spines measure e. g. 9 mm in a specimen with R 81 mm.

In the largest specimen available, R/r 146/29 mm, some scattered small rounded secondary dorsal plates of a size similar to the base of the spines, may be found inserted between the opposite superomarginals, mainly at the sutures between successive plates.

The number of cribriform organs in each interradius is 7 already in the youngest specimen with r 6 mm, very narrow ones, however. Also the medium-sized specimens have as a rule 7 cribriform organs in each interradius. A few specimens with R 60-75 mm and r 12-16 mm have 8 cribriform organs in one or more of the interradii. The specimen with R/r 85/15 mm has 8-9 cribriform organs. The specimen with R/r 118-128/18 mm, and the largest one, with R/r 118-148/29 mm, have 9 cribriform organs in each interradius, and that with R/r about 118-131/20 mm has 11 cribriform organs in some of the interradii. The median cribriform organs may be broadest at the horizontal suture, and possibly

coalesce with their neighbours to one or to both sides.

The terminal ossicle (fig. 14*h*) is fairly high, laterally compressed, and carries in general 3 spines, a terminal one and a pair of usually slightly smaller subterminal ones (occasionally the unpaired terminal spine is the smallest). In the medium-sized and larger specimens the terminal ossicle may sometimes have an additional subterminal spine to one or to both sides of the furrow end. More rarely there is an additional fairly large spine proximally in the dorsal midline. In the largest of the present specimens the terminal ossicle of the only intact normal arm, R 146 mm (fig. 15*g, h*), is very enlarged in height, in ventrad direction (and has a third subterminal spinelet to one side). The whole appearance of this arm indicates that it has stopped growing normally in length, by adding new superomarginal plates, and the peculiar shape of the terminal ossicle in question may thus be interpreted as senescent.

The other arm preserved in this large specimen from st. 235 measures only 118 mm in length, but its outer end is lost in life, and instead of regenerating a new normal terminal ossicle, a substituting terminal end is formed by a pair, it seems, of opposite superomarginals, which have become somewhat thickened and provided with small spines (fig. 15*i, j*). A short distance before the arm end also an extra, similar immitation of a terminal end is formed, probably indicating another place of injury. A third arm in the same specimen is also in regeneration, and has hereby become forked, but during the dredging the distal ends of both forked parts are lost.

Paxillae cover the whole dorsal area of the disk, extending to the marginalia at the arm bases. In the smallest specimens, with R/r 15/6 and 20/8 mm, they are yet rudimentary, consisting only of small roundish plates (the later paxillar shafts) with only a single granuliform spinelet each. In the medium-sized specimens from st. 30, with R about 50-60 mm, the paxillae (fig. 13*d*) carry usually 4-5, and scattered ones as many as 7 granuliform spinelets. In the largest specimens (sts. 234 and 235) the paxillae (figs. 14 *l, m;* 15*b*) usually carry 4-7 spinelets, and scattered ones 8-9. Centrally on the disk there is an area with smaller paxillae, and there may be a faint apical cone, in the small specimens fairly distinct though low.

The madreporic body is roundish, generally with a diameter slightly larger than the length of the neighbouring marginals. It may be separated from these by a few rows of paxillae, but it may also be quite close to them, and pushing itself somewhat in between them in the interradial angle. The striae radiate from an adcentrally located point.

The adambulacral armature is poorly preserved in the two small specimens with R 15-20 mm, but apparently it consists in the main part of the arms of only 3 spines in general.

The proximal adambulacral ossicles in the other specimens with R 35 mm or more (figs. 13*c;* 14*d*) bear along their whole margin a continuous series of usually 5 (6-4) subequal flat spines, generally modified as distinct segmental papillae at a more or less distinctly developed, long, common segmental pit. (These segmental papillae have often the outer thinner calcareous part bent inwards at almost 90 degrees, which it is rather impossible to demonstrate in the drawings). The described appearance of the adambulacral armature changes gradually as one proceeds along the furrow, usually from about the fifth or sixth adambulacral ossicle, but sometimes (in the specimen with R 81 mm e. g.) not until about the tenth ossicles. First, the aboral furrow spine loses the spatulate appearance, becoming longer than the other furrow spines and pointed, the series of furrow spines on these more proximal ossicles still being continuous along the adambulacral margin; and a little farther out on the arms the aboral third of the adambulacral ossicle narrows down somewhat, and the larger aboral spine becomes placed by itself here, whereas the other spatulate furrow spines remain in a continuous row on the adoral part, as segmental papillae over a distinct segmental pit. In the distal half of the arms the difference in the aboral and adoral width of the adambulacral ossicles and the position of the spines becomes very pronounced, but here the adoral furrow spines are pointed and, except for their smaller size, similar to the aboral spine. The number of furrow spines on the distal adambulacralia is often 1-2 smaller than that found on the proximal ones, and thus there are only 3 (or 2) adoral spines besides the larger aboral one.

In some of the large specimens the armature of the more proximal adambulacralia may differ somewhat from what is typical, only the two most adorally placed furrow spines, or only the first, or none at all, being modified as segmental papillae, whereas the remaining spines are all spiniform and pointed like the aboral one, and only slightly decreasing in length from the aboral to the adoral end of the ossicles (fig. 15*d, f*).

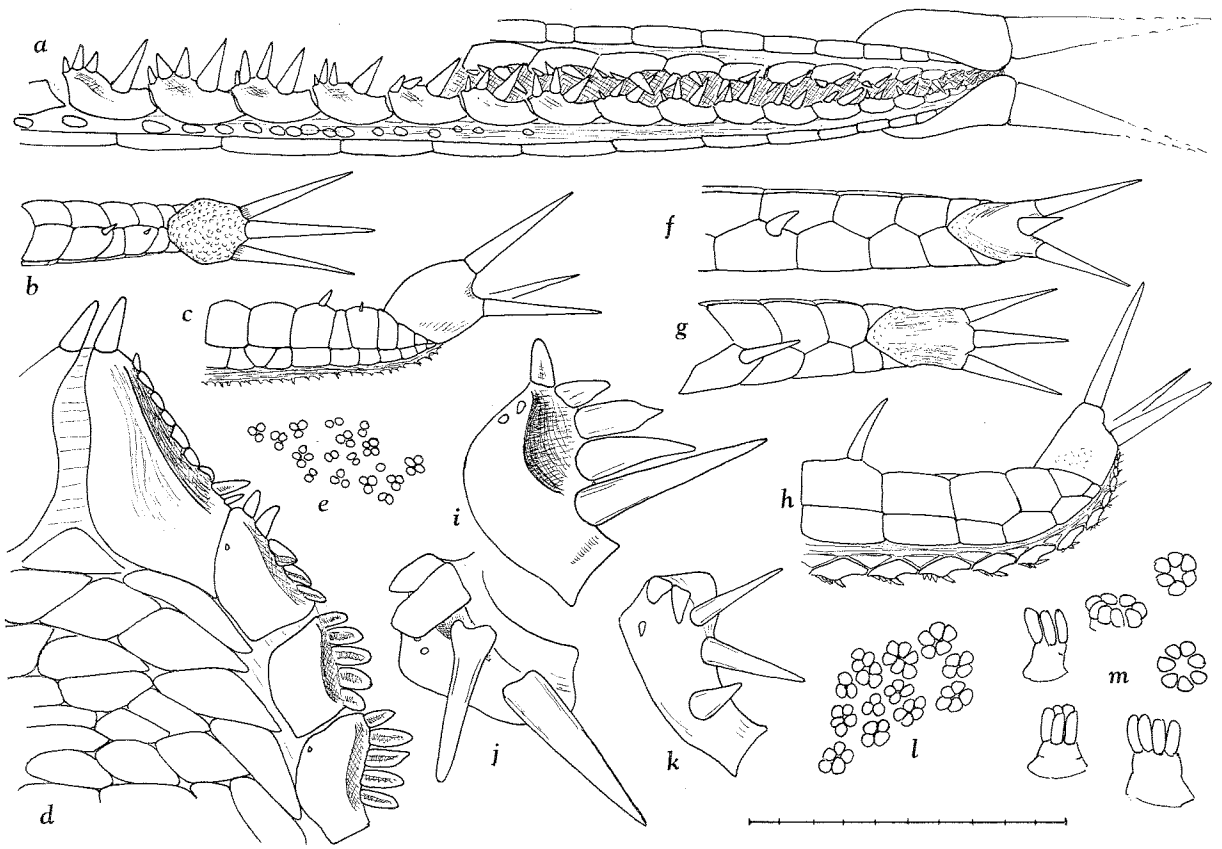

Fig. 14. *Styracaster horridus*. St. 234. a-e) R/r 45/14 mm; a, arm in ventral view in twice the usual scale; b-c, same in dorsal view and in lateral view; d, part of oral side in twice the usual scale; e, paxillae in four times the usual scale. f-m) R/r 118-128/18 mm; f-h, same arm in dorsal view, in oblique dorsal view (with the dorsal side of the terminal ossicle in the plane of the paper), and in lateral view respectively; i-k, adambulacralia nos. 8, 10, and 19 respectively, in twice the usual scale; l-m, paxillae in four times the usual scale.
Scale: 10 mm (in a, and i-k: 5 mm, in e, and l-m: 2.5 mm).

The flattened adambulacral spines (segmental papillae) of the more proximal ossicles, as noted above, have their outer part distinctly bent, and further the calcareous substance of this part is of a looser structure than the basal part, the feature being correlated with that the spines are enclosed in a sheat of skin which may extend far beyond their distal point. LIEBERKIND in 1932 p. 290, went into a detailed, but somewhat obscure discussion of these "spines", and so it may be worth while noting that in their whole structure they seem very similar to the aperture papillae of the pterasterids.

The surface of the adambulacral ossicles of the disk area and proximal part of the arms is provided with a varyingly developed armature, whereas the more distal adambulacralia have a naked surface (which sometimes may apply also to the proximal adambulacralia of the arms, e. g. even in the largest specimen, with R 146 mm). On the most proximal adambulacralia there may be a transverse row of up to 8 spinelets close to the adoral margin, or, more exceptionally, a disarranged group of up to half a dozen granules adorally. The adambulacralia of the inner part of the arms typically carry only 1-2 subambulacral spinelets adorally at the end of the segmental pit.

The ends of the ambulacral ossicles are visible in the whole arm length, simulating small triangular plates wedged in dorsally between successive adambulacralia.

The oral ossicles (figs. 13*c*, 14*d*) bear on their proximal tip a pointed somewhat flattened spine and along their lateral margin a series of about half as long subequal spatulate spines. The proximal spine e. g. is about 1 mm long in a specimen with R 60 mm. The number of marginal oral spines, inclusive of the larger one at the tip, is 7-8 in the smallest specimen with R/r 15/6 mm, and 9-10 in the other small one with R/r 20/8 mm. In the larger specimens the usual number of marginal spines is 10, but there may be 11 and sometimes only 9 marginal spines, the latter number e. g. also in a spec-

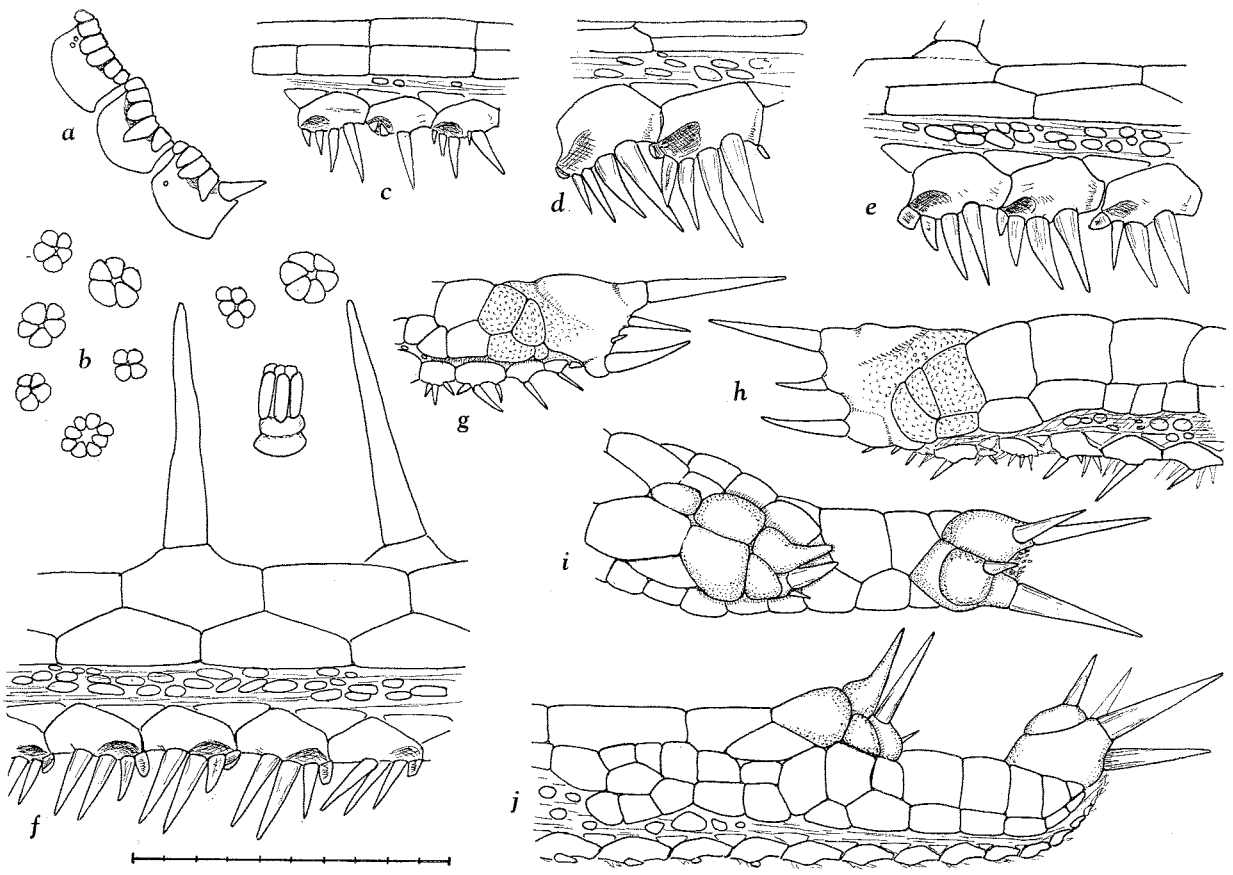

Fig. 15. *Styracaster horridus*. a, St. 234, R/r 128/18 mm, adambulacralia nos. 3-5. b-j) St. 235, R/r 146/29 mm; b, paxillae in four times the usual scale; c-e, parts of same arm in oblique ventral view (with the surface of the adambulacralia in the plane of the paper), showing: c, distal adambulacralia at inferomarginals nos. 25-26; d, proximal adambulacralia at inferomarginal plate no. 8; e, adambulacralia at inferomarginals nos. 13-14; f, part of same arm in lateral view (from the other side), showing the superomarginals nos. 13-14; g-h, distal ends of arms, with the granulated surface indicated on the terminalia and the distalmost marginalia; i-j, an abnormal arm in dorsal view and in lateral view.
Scale: 10 mm (in b: 2.5 mm).

imen with R/r 128/18 mm. Some specimens show in some radii different variations from the typical proximal oral armature of two larger spines, one to each ossicle of the pair forming a jaw. Thus 2 or even 3 of the proximal spines on each oral ossicle may be large and pointed, or there may be an additional unpaired spine between the two normal tip spines, or a jaw may have only such a single proximal larger oral spine, apparently common to the combined pair of oralia forming the jaw.

The surface of the oralia usually appear naked, but there may also be as many as 6 suboral spinelets in a scattered row along the suture and also (or instead) a few spinelets near the distal interradial margin.

The ventral exposed surface of the primary oral ossicle is equilateral triangular in contour.

The ventrolateral plates are transversely elongate and in the more distal part of the interradial area arranged in radiating rows, two and two about corresponding with an adjoining marginal plate. The ventrolateral plates are densely crowded in specimens with empty stomachs, but become well spaced proximally when the specimens are expanded by a full stomach. The ventrolateral plates are still naked in the two small specimens from st. 30, with R/r 15/6 and 20/8 mm, but in all other specimens the ventrolateral area bears a varying number of granuliform spinelets, very scattered in some of the medium-sized specimens, but otherwise in a number of e. g. 6-7 in two tangential rows on each plate, or, as in a large specimen with R/r 128/18 mm, as many as about 20 granuliform spinelets in three tangential rows. Commonly the ventrolateral plates near the margin of the disk are more armed than the proximal ones.

Ventrolateral plates do not yet extend in the arms of the two small specimens from st. 30, R/r 15/6 and

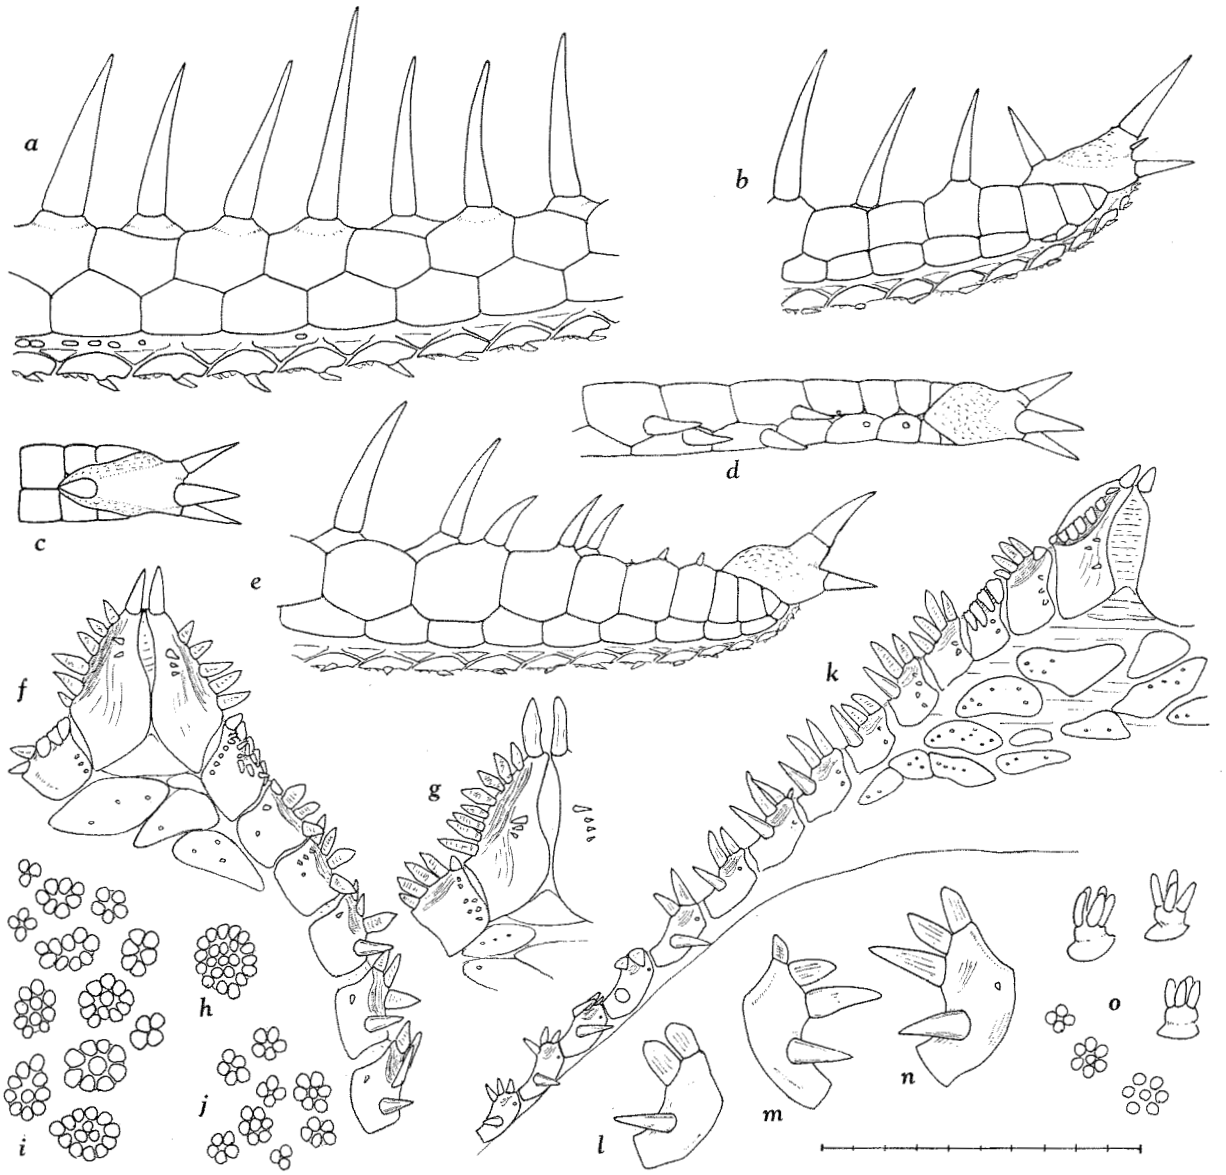

Fig. 16. *Styracaster horridus*. St. 663. a-e) R/r 72/15 mm, (see also k-o); a, part of arm showing the superomarginals nos. 11-18; b-c, distal end of same arm; d-e, another arm in dorsal view and in lateral view. f-j) R/r 74/16 mm; h-j, a large paxilla and two groups of paxillae, in four times the usual scale. k-o) R/r 72/15 mm; l-n, adambulacralia nos. 30, 17 and 15 respectively, in twice the usual scale; o, paxillae in four times the usual scale.
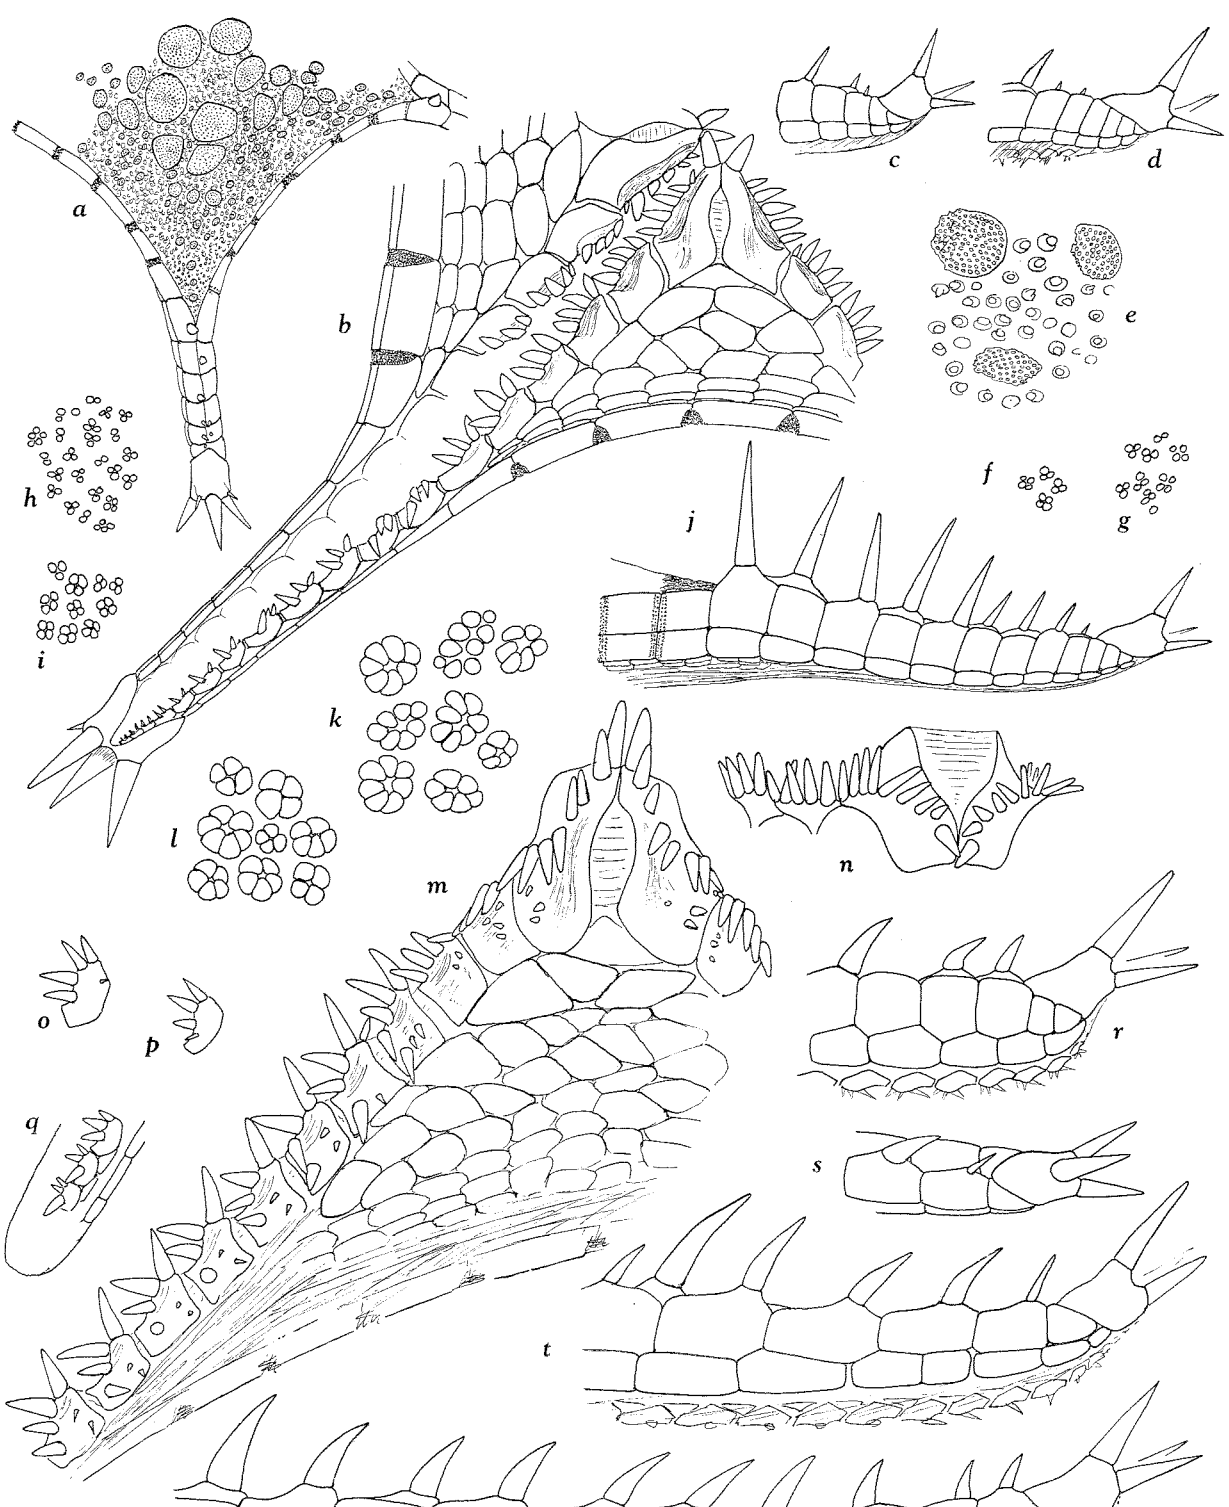
Scale: 10 mm (in l-n: 5 mm, in i-j, and o: 2.5 mm).

20/8 mm, but small rounded ventrolateral plates occur in the larger specimens in a narrow band rather far out in the arms, gradually becoming more and more scattered, so that in about the distal third of the arms there is only a narrow strip of naked skin between the marginal plates and the adambulacral and ambulacral ossicles. Only exceptionally, e. g. in the largest and perhaps senescent specimen with R 146 mm, ventrolateral plates occur also at the tip of the arms. Some of the ventrolateral plates in the arms of the large specimens may be provided with a few granules.

The specimens from the Kermadec Trench (figs. 16, 17; pls. VIII 3-6):

The two specimens of *Styracaster horridus* from st. 663 have R/r about 72/15 and 74/16 mm respectively. The material from st. 664 comprises a single large specimen with R/r 78/20 mm, a detached arm of a second equal-sized specimen, and five smaller specimens, of which one has R/r about 30/8 mm, whereas the others are juveniles with R/r 11/4, 14/5, 16/5, and 21/5 mm.



For the legend to the figure see opposite page.

The adult specimens from the Kermadec Trench:

The number of superomarginals in these three large specimens is 20 in that with R/r 78/20 mm, 26 in that with R/r 74/16 mm, and 24 in that with R/r about 72/15 mm; and the opposite ones join from the sixth, the fifth, and the fourth pair, respectively.

The superomarginals of the arms are typically subquadrate to rectangular, and the accompanying inferomarginals are from three-fifths to less than half as high. In the same specimen there may be a considerable variation in the shape of the marginals in the different arms however, as will appear from the figures 17*t, u* of the distal part of two arms of the specimen with R/r 78/20 mm. In general the marginals are subalternating. The surface of the marginal plates is fairly granulated, especially in the specimen from st. 664. The superomarginals show a faint central depression. The arms may be very compressed.

These three specimens have an almost continuous row of dorsal spines on all arms. There are 18-19 spines on the arms preserved in their total length in the specimens from st. 663 with R about 72-74 mm, whereas the specimen from st. 664 with R/r 78/20 mm has 14, 15, 17, and 18 spines respectively on the four arms and 12 spines on the fifth arm which is in regeneration and only 53 mm long. The arm spines are subequal in length far out on the arms, and generally they are slightly curved towards the arm tip (fig. 16*a, b, e*). The first arm spine is typically developed on one of the plates of the first joining pair of superomarginals, but in one of the specimens from st. 663, it is in two of the arms developed on the plate just before the first one which joins its opposite. The proximal spines are about 6 mm long. Almost without exception the spines are placed with one to each pair of joining superomarginals. Some superomarginals may bear 2 spines, and a large spine may be accompanied by a couple of spinelets near its base.

The cribriform organs number 6-7 in the specimen with R/r about 72/15 mm, 7 in that with R/r about 74/16 mm, and 11 in that with R/r 78/20 mm. The structure is rather sublamelliform.

The terminal ossicles (dorsal to 1-4 superomarginals) carry generally 3 spines, a distal terminal one and a pair of smaller subterminal ones, but some terminal ossicles may have a fourth spine proximally in the dorsal midline (fig. 16*b*).

The whole dorsal area inclusive of the arm bases is provided with close-set paxillae. The number of spinelets in the paxillar crowns is on an average 4-6 in the specimen from st. 664 (fig. 17*l-k*), and 5-7 in that from st. 663 with R/r 72/15 mm (fig. 16*o*), but in both specimens paxillae occur with up to 9 spinelets. The second specimen from st. 663, with R/r 74/16 m, in general has paxillae with 9-12 spinelets (fig. 16*h,j*), but interspersed between these are also many with only 3 granuliform spinelets, and some with as many as 21 spinelets. Centrally on the disk the paxillae are small. None of the specimens show any indication of a central prominence. Neither papulae nor gonopores have been observed.

The adambulacral armature (fig. 16*f, k*) in these specimens is of the general type in *Styracaster,* not being modified as segmental papillae, and there is no distinct segmental pit developed.

The proximal 2-3 (4) adambulacral ossicles in the specimens from st. 663 carry 4, and some of the most proximal ones up to 6 flattened, but pointed furrow spines, the adoral one often smaller than the others. The following adambulacralia in these two specimens carry 4 and 3 furrow spines respectively. The aboral one, which is placed by itself on the narrow part of the ossicles, as usual slender conical and pointed, and the adoral ones of an about similar appearance. The most proximal adambulacralia in these specimens may carry, near their adoral margin, an irregular transverse series of up to 9 granuliform spinelets, and sometimes there are also a few granules on the medial or aboral part of the ossicles. The following adambulacralia within the disk area and in the proximal part of the arms, carry 1-2 subambulacral granules adorally, whereas the more distal ambulacralia have a naked surface.

In the specimen from st. 664 with R/r 78/20 mm (fig. 17*m*), the proximal two subrhomboid adambulacralia carry a uniform series of 4-5 furrow spines and adorally on their surface a small number

Fig. 17. *Styracaster horridus*. St. 664. a-b) R/r 14/5 mm; b, part of ventral side in twice the usual scale. c) R/r 16/5 mm. d) R/r 21/5 mm. e) R/r 16/5 mm, part of dorsal skeleton in four times the usual scale. f-g) R/r 21/5 mm (see also j), two groups of paxillae in four times the usual scale. h-i) R/r ab. 30/8 mm, two groups of paxillae in four times the usual scale. j) R/r 21/5 mm. k-q) R/r 78/20 mm (see also s-u); k-l, two groups of paxillae in four times the usual scale; o, p, q, adambulacralia nos. 20 26, and 32-34 respectively. r) Arm end of large specimen. s-u) R/r 78/20 mm; s-t, distal end of same arm in dorsal view and in lateral view; u, another arm in side view.
Scale: 10 mm (in b: 5 mm, in e-i, and k-l: 2.5 mm).

of subambulacral granuliform spinelets. The following few adambulacralia of the disk area bear adorally on their surface, in line with the one or two adoral subambulacral spinelets, a spine subequal to the furrow spines, and judging from the condition of the spine armature of the more distal adambulacralia, better considered as a distal furrow spine moved unto the subambulacral surface than as a real subambulacral spine. In the arms the adambulacral armature of 4 spines is positioned in the usual way, with all at the furrow margin, but the aboral spine is not larger, and perhaps even smaller than the adoral ones. The most distal adambulacralia, however, have not yet this aboral spine developed. In the present specimen with about 38 adambulacralia, those about no. 26 are the first with the aboral spine present, and not until the ossicles about nos. 20-18 does it reach a size as that found in the proximal part of the arms. An adoral subambulacral spinelet may be present on the ossicles far out in the arms.

The oral ossicles of the specimens from st. 663 (fig. 16*f, k*) are provided with from 6 to 9 marginal spines, the proximal one two or three times as long as the lateral ones, which are flattened and with a more or less pointed end. In one specimen there are oralia with 6, 7 and 9 marginal spines respectively. The oral spines are not modified as segmental papillae, and there is no distinct segmental pit. Both specimens bear on all oralia a fairly large suboral spine medially near the suture, and on some oralia there are a few additional suboral spinelets in a sutural row.

The oral ossicles in the specimen from st. 664 with R/r 78/20 mm (fig. 17*m*) bear 8-10 marginal spines, which are larger than is usually the case in the species, and although slightly flattened, rather terete. The proximal spine, about twice as large as the lateral ones, is placed a trifle higher on the ossicle (i. e. deeper in the mouth) than the others, the series of which extends below it almost to the suture. Each oral ossicle thus have two spines at its proximal end. Distally on their surface the oralia may bear up to 5 suboral spines. The primary oral ossicle shows the same, equilateral triangular ventral surface as in the Atlantic and Indian specimens.

The ventrolateral plates in the specimens from st. 663 are arranged in 7-10 tangential series and extend into the arms, reaching as far as to the marginals nos. 12-14. The ventrolateral plates of the disk area may carry up to about ten minute granules. In the specimen from st. 664, with R/r 78/20 mm, small ventrolateral plates extend in the arms as far as to the marginals no. 13. The ventrolateral area in this specimen appears to be devoid of granules.

The juvenile specimens from the Kermadec Trench:

The larger one of the remaining specimens of *Styracaster horridus* from st. 664, R/r about 30/8 mm and ≧ 30 superomarginals, has about the same characters as the full-grown specimens described. The superomarginal plates of the arms are rectangular, joining from plates no. 6. One arm, with the end lost, carries a continuous row of 8 dorsal spines, one to each pair of joining superomarginals. There are 7 cribriform organs in each interradius, and in one case an additional rudimentary one, yet consisting of only a single row of paxillae. The dorsal paxillae bear 3-4 spinelets. The number of furrow spines is 4-5 on the first adambulacral ossicle, 4 on the following ones, and 3 on those of the arms, all the furrow spines being straight and pointed. The oralia carry 6 marginal spines, flattened but all straight and pointed, not forming segmental papillae. The spine at the tip of the ossicle is as usual the largest. Ventrolateral plates occur in the arms at least as far as to the inferomarginals no. 8. The surface of the ventrolateral plates and of the oralia is naked, whereas there is a minute spinelet adorally on the surface of some of the adambulacralia in the arms.

The other four small specimens all show juvenile characters. They have R/r 11/4, 14/5, 16/5, and 21/5 mm, and 7-9, about 10, 11-12, and 14 superomarginal plates respectively, joining from plates no. 4 (or 5, in some arms of the smallest specimen). The number of arm spines is 2-4 in the specimen with R 11 mm, 3-4 in that with R 14 mm, 3-6 in that with R 16 mm, and 9 on the single intact arm of the specimen with R 21 mm. The cribriform organs number 3-5, 5-6, 7, and 5-7 respectively. The 3-5 cribriform organs in the specimen with R/r 11/4 mm are all still quite rudimentary, consisting only of a double row of papillae, one series to each side of the vertical marginal sutures. Similarly the outermost cribriform organs in the other specimens are only rudimentary. The terminal ossicles bear 3 spines in two of the specimens, and 5 spines in the two smallest ones, viz. a distal terminal one, a pair of slightly smaller subterminal ones, and dorsally on the ossicle a pair of very minute ones close to the unpaired terminal one. The first adambulacral ossicle carry 4-5 lanceolate furrow spines (5 in the smallest specimen), the following ones 3, and the most distal ones perhaps only 2 furrow spines. There

is no subambulacral armature. The oral ossicles carry 6 (in some cases 7) lanceolate marginal spines, the proximal one the largest. A suboral armature is not developed except for a minute spinelet on one of the ossicles of the specimen with R/r about 16/5 mm. The ventrolateral plates, which are also naked, extend just into the proximal part of the free arms, in the specimen with R/r 21/5 mm e. g. to opposite the sixth inferomarginals.

The dorsal armature of these small specimens from st. 664 shows the gradual change from juvenile to adult state. In the specimen with R/r 11/4 mm there seems to be yet almost only the juvenile (embryonic) skeleton developed, consisting of the large embryonic (primary) plates and with smaller, supplementary (secondary) plates interspersed between them; only some very small plates, which probably are to be interpreted as the later paxillar shafts, are also present. The large embryonic plates are also still present in the specimen with R/r 14/5 mm, but further there are here numerous rudimentary paxillae, their number exceeding that of the small supplementary embryonic plates, many of them carrying a single granuliform spinelet, others yet consisting of the later paxillar shafts. In the specimen with R/r 16/5 mm the large embryonic plates are in absorbtion (fig. 17*e*), and the paxillae are still rudimentary and with only a single spinelet. In the specimen with R/r 21/5 mm the embryonic plates are entirely absorbed, and many paxillae have up to 4 spinelets, though all of them still very small (fig. 17*f, g*).

Concluding remarks: LUDWIG considered the peculiar adambulacral and oral armature of his specimen a specific character. The same kind of armature, however, was actually found in the type-specimen of *Styracaster horridus*. The present material also shows that this characteristic appearance of the furrow armature, with the adoral spines modified as a kind of segmental organ, is of no definite importance in the specific diagnosis, since individual specimens may show the more usual porcellanasterid armature with spiniform instead of spatulate furrow spines. (The specimens at hand from the Kermadec Trench show the latter feature, besides transitional stages). It will appear from the following discussion of *Eremicaster* that segmental organs (papillae and pits) form an unstable character also in this genus.

The presence of ventrolateral plates in the arms, which was believed to distinguish *Chunaster* from *Styracaster,* is also an individually variable character (such as is also the possible presence of secondary dorsal arm plates in *Thoracaster*). In the juvenile specimens with R up to about 20 mm, ventrolateral plates may occur in the most proximal part of the free arms, as far as to the sixth inferomarginals, but they may also be entirely absent. In the large specimens ventrolateral plates usually occur in the proximal two-thirds of the arms, but may likewise be entirely absent, as in the two specimens available from the Galathea st. 282, and in SLADEN's specimen. In some specimens, as e. g. the largest one available, R 146 mm, ventrolateral plates extend in the arms clear to the terminal ossicle. The ventrolateral skeleton in the arms may appear as a single series of fairly large subquadrate plates forming a regular pavement of the narrow area between the inferomarginal plates and the adambulacral and ambulacral ossicles, as e. g. in one of the arms of a large specimen from st. 664 (fig. 17*u*), or as a double series of relatively smaller rectangular plates, as in LUDWIG's specimen, or there is one or more series of small oval or rounded plates, being gradually more and more spaced as they proceed outwards in the distal part of the arms (fig. 15*c-f*).

Biological remark:

Eggs, 0.5 mm in diameter, were found in the gonads of one of the larger specimens from st. 664.

Distribution:

Styracaster horridus is known hitherto from 15 dredgings: nine in the Eastern Atlantic, from the Bay of Biscay to the Gulf of Guinea; four in the northern Indian Ocean; and two in the South Pacific north of New Zealand (fig. 34). The known bathymetrical distribution is from 4040 to 5610 m. The kind of bottom on which it has been collected is sandy clay, calcareous clay, mud, muddy ooze, and globigerina or radiolarian ooze. The temperatures recorded range from 1.1° to 2.4° C.

S. horridus WOOD-MASON & ALCOCK 1891*b*, p. 434; ALCOCK 1893 p. 86. (Non *S. horridus* Sladen).

LUDWIG diagnosed this species on the basis of a single specimen collected by the Valdivia Expedition

in the Indian Ocean, east of Zanzibar (st. 240: 6°12′S, 41°17′E, 2959 m, globigerina ooze, 2°C.). It has R/r 65/13 mm; 20 superomarginals; 14-16 dorsal arm spines, the proximal two of which are placed side by side in an oblique row; 7 cribriform organs; terminal ossicle with 3 spines. Closely crowded small paxillae with 3-4 granuliform spinelets; a low apical cone. Adambulacralia with 3 furrow spines; oralia with 6 marginal spines. Ventrolateral plates naked.

LIEBERKIND (1932) in the final report on the Valdivia porcellanasterids published some detail figures of the same specimen, but did not discuss it more closely and did not give any illustrations of its general appearance, finding this superfluous, since the specimen agreed well with those from the Investigator collections described in the meantime by KOEHLER. However, since it is useful to have photographs of type-specimens published, two photos from the archives of the Zoological Museum of Copenhagen are reproduced in figs. 1-2 pl. IX, showing the type-specimen of LUDWIG's *S. caroli* in ventral and in dorsal view respectively.

The three specimens of *S. caroli* which were described by KOEHLER in 1909 came from three dredgings of the Investigator in the Bay of Bengal (st. 117: 11°58′N, 88°52′E, 3197 m, globigerina ooze, 1.8°C.; st. 118: 12°20′N, 85°08′E, 3298 m, globigerina ooze, 1.7°C.; and in 6°18′N, 90°40′E, 2780 m). Those from stations 117 and 118 were previously recorded by WOOD-MASON & ALCOCK in 1891 (and ALCOCK 1893) but erroneously identified with SLADEN's *Styracaster horridus*.

The three Investigator specimens were apparently of about equal size. That from st. 118 has R/r 53/12½ mm; 20 superomarginals, longer than high, joining from plates nos. 4-5. A continuous series of dorsal arm spines (e. g. 12), the two larger proximal ones sometimes placed side by side as described for the type, but such an arrangement not always distinct. Seven cribriform organs. Terminal ossicle dorsal to two superomarginals, twice as long as broad, convex dorsally and with 3 short spines. Whole dorsal side with small paxillae with 3-4 granuliform spinelets. Adambulacral ossicles (32 in number) rectangular, proximal one with 4 conical pointed furrow spines, the adoral of which the longest, following ones with 3 furrow spines, the aboral of which isolated on the narrower part of the ossicle. No subambulacral armature except for an adoral granule on first to third ossicles. Oral ossicles with 7-8 marginal spines, lateral ones rather subequal to the furrow spines, proximal one larger; in general no suboral armature, only in one specimen 1-3 spines along the suture. Ventrolateral plates completely naked, arranged in about 5-6 tangential rows and further in radiating rows, not extending outside disk area.

WOOD-MASON & ALCOCK noted that specimens with the stomach empty show an apical cone, whereas none is seen when the stomach is distended. They record the colour in fresh state as "pale yellowish pink".

The Galathea material:

The species *Styracaster caroli* was collected in two dredgings in the Indian Ocean, north of Madagascar and in the Bay of Bengal respectively.

St. 234: 5°25′S, 47°09′E, 4820 m., 1.8°C. 2 specimens.

St. 314: 15°54′N, 90°17′E, 2600 m., 1.7°C., brownish ooze. 1 specimen.

The two specimens from st. 234 have R/r 93/about 24 (pl. IX 3-4) and 93-100/about 21 mm respectively. That from st. 314 has R/r 72/17 mm.

The number of superomarginals is 22 in the specimen with R about 72 mm, 26 in that with R 93 mm, and 27 in that with R up to 100 mm. The superomarginals join their opposites from plates nos. 5-6. The surface of the marginal plates is granulated. The proximal superomarginal plates of the arms are about one and a half time as long as high, and the inferomarginal plates are about half as high as the accompanying superomarginals. The superomarginals of either side of the arm may be almost regularly opposite each other, but usually they subalternate, and sometimes they are very regularly alternating, with the suture between them forming a zig-zag line (fig. 18 *a*). Similarly the inferomarginals may correspond as well as alternate regularly with the superomarginals. As usual in the porcellanasterids the arrangement of the marginal plates may vary in the different arms of the same specimen. The larger dorsal arm spines are generally borne on distinct knobs on the plates.

The number of arm spines is 15 and 19 in the two intact arms of the specimen with R 72 mm, and 24-25 in the specimen with R 93 mm (pl. IX 5). The specimen with R 93-100 mm has 36 spines developed on one arm 95 mm long, and 22-27 spines on the other arms. In the specimens from st. 234 each of the plates of the first joining pairs of superomarginals bears a well developed spine (e. g. 8½ mm

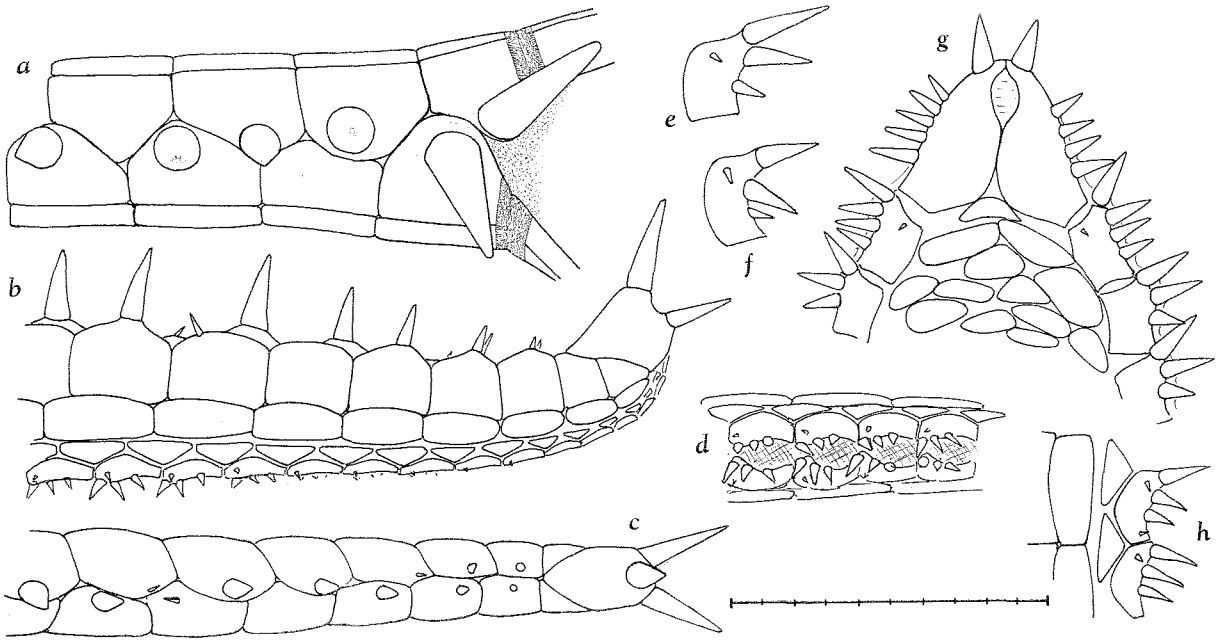

Fig. 18. *Styracaster caroli*. a-f) St. 234, R/r 93/ab.24 mm; b-c, distal end of arm in side view and in dorsal view; d, part of, same in ventral view; e-f, adambulacral ossicle no. 2, and one from the median part of the arm. g) St. 314, R/r 72/17 mm. h) St. 234, R/r 93-100/ab.21 mm, adambulacral ossicles from the median part of the arm, shown with their surface in the plane of the paper.
Scale: 10 mm.

long or almost as high as the arm), and at each arm base there are thus two subequal large spines somewhat displaced in relation to each other and widely diverging (fig. 18*a*). In the specimen from st. 314 there are two spines developed at one arm base (one spine to each of the plates in the first joining pair of superomarginals), whereas there is only a single spine at the two other arm bases. (The two remaining arm bases are torn away).

The arm spines are arranged in a straight continuous series in the midline for the whole, or at least the greater length of the arm, perhaps with only a single spine to each of the opposite pairs of superomarginals, but often with a spine on every plate in the then more or less regularly alternating series on either side of the arm. There may be a single series of arm spines clear to the terminal ossicle, but distally in some arms the yet rudimentary arm spines form a double row, a varying number of the distal superomarginals being opposite each other. Some superomarginals may bear two spines, but the additional one is generally only small. The arm spines decrease gradually and more or less regularly in length towards the end of the arms, and distally they are only rudimentary.

The cribriform organs number 9 in each interradius of the specimen with R/r 72/17 mm, 10-11 in the specimen with R/r 93-100/about 21 mm, and 11 in that with R/r 93/about 24 mm. The 9 median cribriform organs are well developed, whereas the possible additional ones are only rudimentary. The median cribriform organs comprise up to about 24 rows of papillae, and may almost touch their neighbours, leaving only a very narrow strip bare medially on the marginals.

The terminal ossicles are elongate, laterally compressed, dorsal to about two superomarginals, and provided with 3 spines, a moderately long distal terminal one, and a pair of slightly smaller subterminal ones (fig. 18*b*).

The whole dorsal area is covered with small paxillae with 3-4 short spinelets. The central area with smaller paxillae may be elevated into a faint apical cone. Papulae were not observable in any of the specimens. (LUDWIG, in his diagnosis of the species, stated that papulae were not present.)

The madreporic body is subcircular, with the striae radiating from an adcentral point.

The adambulacral ossicles in the disk area are subrectangular, but in the arms they become subcrescentic and more elongate. The triangular ends of the ambulacral ossicles are in the arms very conspicuous between the series of adambulacralia and inferomarginalia. The first adambulacral ossicle carries 3 or, in the specimen from st. 314, 4 conical pointed furrow spines (fig. 18*g*). The follow-

ing adambulacralia all carry 3 furrow spines, with two close together on the adoral part of the ossicle and the third smaller one medially on the ossicle, often a small distance from the adoral ones. The furrow spines of the disk area are larger than the proximal lateral oral spines. In the most distal part of the arms there may be only 2 adambulacral spines.

In the specimen from st. 314, with R 72 mm, a few of the proximal adambulacralia carry a minute subambulacral spinelet close to their adoral margin, whereas the other adambulacralia have a naked surface. In the two specimens from st. 234 with R 93 to 100 mm, nearly all the adambulacralia, almost to the tip of the arms, carry such an adoral subambulacral spinelet, and some of the proximal adambulacralia may bear two such spinelets (fig. 18*e, f, h*). In the specimen with R/r 93-100/about 21 mm, scattered adambulacralia may further bear a minute aboral subambulacral spinelet.

The oral ossicles (fig. 18*g*) are provided with 5-6 conical pointed marginal spines, the proximal one the largest; and the rather subequal lateral ones about half its size in the specimens from st. 234, but almost as long, though much more slender, in the specimen from st. 314. A suboral armature is not developed. The primary oral ossicle has a broadly triangular exposed surface.

The ventrolateral plates are transversely elongate, arranged in up to about 12 tangential rows in the specimen from st. 314, and in from about 10 up to about 15 indistinct tangential rows in the larger specimens from st. 234. Further they are arranged in more or less distinct radiating rows which correspond two and two with an adjoining marginal plate. They do not extend outside the disk area. The whole ventral area, including the ventral side of the arms, has been covered by a fairly thick integument, which, however, for the greater part has been rubbed off. The ventrolateral area appears completely devoid of granules or spinelets in the two specimens, but a few granules were found scattered in that with R 93-100 mm.

Remarks:

The present specimens of *Styracaster caroli* are somewhat larger than those hitherto known, and show correspondingly a larger number of cribriform organs and of dorsal arm spines. Otherwise they agree well with the type described by LUDWIG as well as with the specimens described by KOEHLER. It appears from the present material that the very characteristic doubling of the dorsal spines at the arm bases, found in the type from near Zanzibar and also in the two Galathea specimens from a more easterly locality, is not a reliable specific character, since it is not developed in some of the radii in the Galathea specimen from the Bay of Bengal, and was sometimes indistinct in KOEHLER's specimens from the Bay of Bengal.

Styracaster caroli in general appearance very much resembles *S. horridus*. It is distinguished from this species primarily by the character of the adambulacral armature.

Distribution:

Styracaster caroli is hitherto only known from the Indian Ocean (fig. 35), viz. from two dredgings in the area east of Zanzibar, and from four dredgings in the Bay of Bengal. It has been found in depths from 2600 to 4820 m, at temperatures of 1.7° to 2°C., and on a bottom of globigerina ooze and brownish ooze.

Styracaster elongatus, KOEHLER 1921 p. 2.
Styracaster horridus, RICHARD 1903 p. 66 (Non *S. horridus* Sladen).

KOEHLER described this species from a specimen with R/r ≧ 100/about 18 mm, dredged by the Princesse Alice in the Atlantic near the Azores (st. 1306: 37°17'N, 20°14'W, 4275 m, globigerina ooze). The specimen is mentioned previously in the literature, by RICHARD in 1903, but at that time erroneously considered a *Styracaster horridus,* and the station no., by a printers slip, given as 1036. KOEHLER in 1907, in his preliminary report on the Princesse Alice material, records also a second specimen, R/r ?/17 mm, from a neighbouring locality (st. 753: 39°52'N, 18°01'W, 4360 m, globigerina ooze), and in 1909, in the final illustrated edition of the report, he records still another specimen, R/r 55-60/13 mm, from a third locality in the same area (st. 527: 38°09'N, 23°17'W, 4020 m), besides an additional specimen, R/r ?/about 19 mm, from the station 753. (By a printers slip KOEHLER in 1909 gives the depth at st. 753 as 5360 instead of 4360 m). In 1921 KOEHLER finally records 3 specimens of *S. elongatus* from two Princesse Alice dredgings in the Bay of

Biscay (st. 2948: 46°46′N, 5°50′W, 3910 m, sandy mud; and st. 2986: 45°08′N, 7°06′W, 4870 m).

The type-specimen with R/r ≧ 100/about 18 mm, has 30-35 superomarginal plates, joining their opposites from no. 4. Marginals of disk slightly higher than long; superomarginals in arms slightly longer than high, inferomarginals somewhat lower. Up to a dozen conical pointed arm spines, confined to about the proximal two-third of arms. (In the type slightly curved away from the disk; but according to figures the reverse sometimes the case proximally in arms of other specimens). Seven cribriform organs. Terminal ossicle fairly conspicuous, with 3 spines. Closely crowded paxillae with 4-6 spinelets. A small apical cone. Adambulacralia with 5 fairly long furrow spines, and those of disk and proximal half of arms with 1-2 spinelets adorally and 1 small spine aborally on their surface. Oralia with a dozen marginal spines, the proximal of which by far the largest, and 2-3 suboral spinelets along sutural and 3-4 along distal margin. Ventrolateral plates in about 9 tangential rows, not extending outside disk area, and apparently naked. – In another large specimen from st. 753 they carry 1-3 small granules.

The specimen with R/r 55-60/13 mm has about 25 superomarginals, half a dozen arm spines (distal part of arms unarmed), and 5 cribriform organs. Adambulacralia with 4 furrow spines; proximal ossicles without subambulacral spines, but following ones with a single small spine aborally. No suboral armature. Ventrolateral plates apparently naked.

The Galathea material:

Specimens of *Styracaster elongatus* were collected in two localities in the Indian Ocean, in the Mozambique Channel, and south of Ceylon respectively.

St. 217: 14°20′S, 45°09′E, 3390 m, 1.6°C., globigerina ooze. 1 specimen.

St. 281: 3°38′N, 78°15′E, 3310 m, 1.8°C., globigerina ooze. 4 specimens.

R/r are in the specimen from st. 217 (pl. X 1-2) 74/18 mm, and in those from st. 281 about 55/14, 80/19, ≧ 80/21, and 81/23 mm.

The superomarginals number 23 in the specimen with R/r 55/14 mm, 26-27 in that with R/r 80/19 mm, and 27 in that with R/r 74/18 mm as well as in that with R/r 81/23 mm. The superomarginals join their opposites in the midline of the arm from plates nos. 5-6, or, in the specimen with R/r 80/19 mm, from nos. 4-5.

The superomarginals in the arms are subquadrate and the accompanying inferomarginals somewhat lower, being about one and a half times as long as high. All the marginals have a finely granulated surface, and their calcareous substance seems to be of a fairly porous structure. The superomarginals of either side of the arms may correspond as well as subalternate, and similarly the inferomarginals in the arms may sometimes alternate with the superomarginals to a varying degree.

The specimen from st. 217, with R 74 mm, has 4 dorsal spines on one arm, and 3 spines on the three other arms preserved. One of the larger specimens from st. 281, with R 80 mm, has 4 spines on two arms and 5 spines on the third arm left, whereas the specimen with R ≧ 80 mm has 2 spines on two of the arms and only a single spine on each of the other three arms, and the two remaining specimens, with R 81 and 55 mm, only a single spine to each of the five arms. There is always a spine at the arm base, placed on one of the plates of the first joining pair of superomarginals, and the possible additional spines are always found on plates of the more proximal part of the arms, so that the distal main part of the arms is unarmed. The first arm spine is always fairly robust, but not very long, its length being less than the height of the arm. It may be more or less distinctly curved towards the disk, whereas the other arm spines are straight and slightly curved against the arm end. The proximal arm spine in one of the large specimens is peculiar in having a broad flange on its distal side, which gives it a fan-shaped appearance.

The cribriform organs, which are of a papilliform structure, number 7-8 in the specimens with R/r 55/14 and 80/19 mm, the eighth additional one being rudimentary, 8-9 in the specimens with R/r 74/18 and 81/23 mm, and 9 in all the interradii of the specimen with R/r ≧ 80/21 mm.

The terminal ossicle (fig. 19*c, d, k*) is elongate, laterally compressed and with 3 spines, a terminal one about as long as the ossicle itself and a pair of somewhat smaller subterminal ones. The ossicle is dorsal to 2-4 superomarginals, and is most conspicuous in the smallest specimen, with R 55-60 mm.

The whole dorsal area, including the arm bases, is covered with close-set paxillae (fig. 19*e*). In the specimen from st. 217 the paxillae carry on an average 7-8 spinelets, but larger ones with up to 14 spinelets occur scatteredly. In the specimens from st. 281 the paxillae are generally smaller, with 4-7 spinelets, and the largest one observed in the differ-

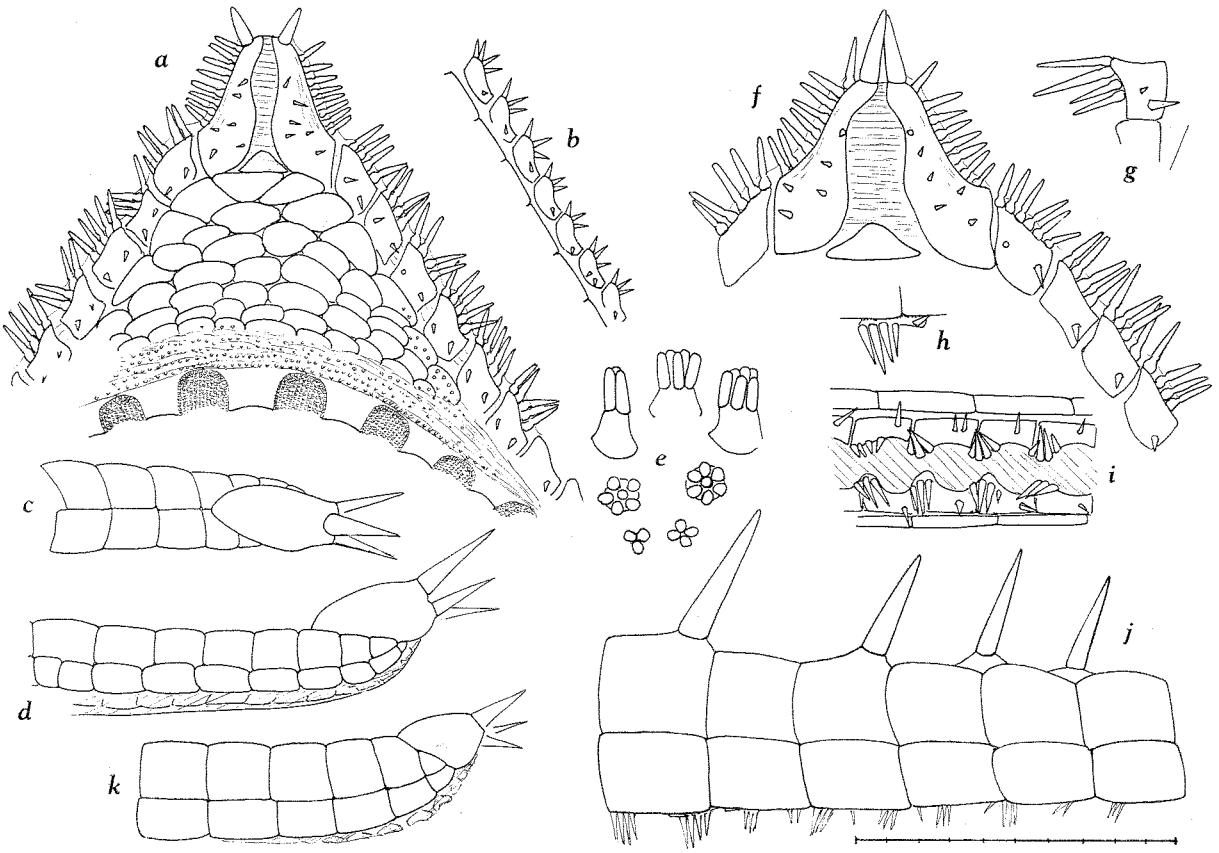

Fig. 19. *Styracaster elongatus*. St. 281. a-e) R/r 55/14 mm; a, part of ventral side (the figured interradius apparently shows the abnormal condition of having an odd marginal plate mid-interradially, instead of a suture. Another interradius shows the same feature, whereas the remaining three interradii in the specimen show the typical mid-interradial sutures); b, adambulacralia nos. 17-23, at the inferomarginals nos. 12-17; c-d, distal end of arm in dorsal view and in side view. f-j) R/r ≧ 80/21 mm; g, adambulacral ossicle no. 7; i, part of arm in ventral view, showing the inferomarginals nos. 8-10; h, one of the same adambulacralia figured with the furrow spines in the plane of the paper; j, proximal part of arm, showing the superomarginals nos. 8-13. k) R/r 81/23 mm.
Scale: 10 mm (in e: 2.5 mm).

ent specimens have 7, 8, 9, and 11 spinelets respectively. The central area of the disk, with smaller paxillae, may be elevated into a faint apical cone.

The madreporic body is circular, of a diameter about equal to the length of the adjoining marginals, and separated from these by a single row of paxillae. Its striae radiate from an adcentral point.

Papulae were observed in a small number on the outer half of the disk to each side of the mid-interradial line in a couple of the specimens from st. 281 which have the dorsal area well expanded by a full stomach. Their size is about twice that of the paxillar spinelets.

The proximal subrhomboid adambulacral ossicles (fig. 19*a,f*) carry a series of (4-)5, (exceptionally, in one arm of a large specimen, 6) subequal slender and generally rather terete furrow spines with a slightly enlarged basal part imbedded in a common web along the whole furrow. The adambulacralia of the arms generally have 3-4 furrow spines placed close together on the protruding adoral part. If there are 3 spines, the adoral one is often slightly larger than the others, if there are 4 spines, the second adoral one is often the largest (fig. 19*g*). On their surface the adambulacralia of the disk area, and sometimes those of the proximal part of the arms, carry two spinelets, a small adoral one and a larger aboral one. Exceptionally the first ossicle may carry 2 adoral spinelets, thus 3 subambulacral spinelets in all. In the main part of the arms only the aboral subambulacral spine is developed, possibly reduplicated on some ossicles, and most distally in the arms the surface of the ambulacralia is yet naked.

The oral ossicles (fig. 19*a,f*) of each pair forming a jaw are separated by a broad suture, and the primary oral ossicle is well exposed, showing a broad triangular ventral surface. Each oral ossicle

carries 8 or 9 marginal spines, that at the proximal end much stouter and up to twice as long as the lateral ones, which are subequal, slender, fusiform, and slightly smaller than the proximal adambulacral spines. (One of the oralia in the specimen with R/r 80/19 mm is provided with two proximal spines, one above the other). Further the oralia carry a number of suboral spinelets, 2-4 along the suture, and also 2-4 near the distal margin.

The ventrolateral area is paved with comparatively small plates, in general transversely elongate, though not always so markedly as is usual in other species of *Styracaster,* and arranged in indistinct tangential and radiating series. Two radial series of ventrolateral plates may correspond in width with a marginal plate, but usually the number of plates is increased in the most distal tangential series so that 3 or 4 correspond with an adjoining marginal plate. The ventrolateral plates near the margin of the disk may be well provided with minute granules, and such may also occur scatteredly on the other plates. The main part of the ventrolateral area, however, usually appear naked, and this applies to the whole ventral area of one of the large specimens, but perhaps this is a matter of preservation, possible spinelets may be easily lost, and also the whole covering ventral integument is easily rubbed off.

The proximal ventrolateral plates are in general not markedly larger than the more distal ones, often only about twice their size, and though this is somewhat variable it appears to be a specific characteristic of the species. Ventrolateral plates do not extend outside the disk area.

The specimen with R/r 55/15 mm, st. 281, shows in three of the arm angles the normal mid-interradial suture, whereas to all appearance (cf. fig. 19*a*) there is in the two other arm angles a marginal plate in the interradial midline.

In general appearance *Styracaster elongatus* resembles *S. horridus* and *S. caroli.* It is best distinguished from these by the character of the adambulacral armature.

Distribution:

Styracaster elongatus is known at present from seven dredgings (fig. 35): five in the eastern North Atlantic, the Bay of Biscay and near the Azores; and two in the Indian Ocean, west of Madagascar and south of Ceylon. Its known bathymetrical distribution is from 3310 to 4870 m. The bottom on which it has been collected is globigerina ooze and sandy mud, and the recorded temperatures 1.8°C.

Styracaster chuni Ludwig, 1907

Styracaster sp., Ludwig, in Chun 1900 p. 491, fig.
S. chuni n. sp., Ludwig 1907 p. 314.
S. chuni, Lieberkind 1932 pp. 276-281, text-figs. 5-7, pls. 1_{3-4}, 4_{2-6}, 6_{12-15}. 1935 pl. 5_{5-5a}, 8.
S. chuni var. *groenlandica* n. var., Lieberkind 1935 pp. 26-29, text-figs. 9-10, pls. $1_{1-3,6}$, 3_{13-16}, 4_{10-13}, 5_{6-7}.

Ludwig diagnosed this species on the basis of three specimens dredged by the Valdivia in the Atlantic, in the Gulf of Guinea (st. 63: 2°00′N, 8°04′E, 2492 m, 2.6°C.); and the same specimens were treated somewhat more exhaustively, and also figured, by Lieberkind in 1932. Lieberkind, in 1935, further described 12 specimens of *S. chuni* collected by the Ingolf in the southern part of Davis Strait (st. 37: 60°17′N, 54°05′W, 3229 m, 1.4°C.), which specimens he, however, considered represented a new variety.

The three Valdivia specimens (the type-material) have R/r ranging from 41/14 mm over R 44 mm to 57/19 mm; 12-14 subquadrate superomarginals, joining from plates no. 5; inferomarginals only half as high as long, all marginals with a finely granulated surface; 2-5 large pointed arm spines; 5-7 cribriform organs. Terminal ossicle elongate, laterally compressed, with 3 spines, a large distal one and a pair of smaller subterminal ones. Dorsal paxillae uniform, small, close-set, with 4-6 (-8) spinelets, not present in arm bases, however, where there is a pavement of naked plates. No distinct apical cone. Madreporic body round, with striae radiating from adcentral margin. Adambulacralia with a curved furrow margin, with 3 (sometimes 2 and proximally perhaps 4) pointed furrow spines, and with 1-2 (3) subambulacral spines, viz. an aboral one, generally fairly large and only in rare cases absent, and on the more proximal ossicles usually one or two adoral ones. Oralia with 4-6 marginal spines, proximal one twice as large as lateral ones, and a few suboral spinelets near sutural or distal margin. Ventrolateral plates naked, arranged in 6-9 tangential rows, not extending outside disk area. Ventral area covered by a thick integument.

Of the twelve Ingolf specimens recorded by Lieberkind (1935), one has R 52 mm, 15 superomarginal plates, and 7 cribriform organs; another of about the same size has only 5 cribriform organs in each interradius, but one with R only 24 mm has also 7 cribriform organs developed, though the

outermost ones rudimentary. The number of dorsal spines on each arm varies from 1 to 6.

LIEBERKIND described these specimens as representing a new variety, var. *groenlandica,* which he considered distinguished from the typical form by having smooth, or almost smooth marginal plates, and by having higher paxillar shafts and more slender paxillar spinelets. The specimen on which LIEBERKIND seems to have based his description of the variety, R 52 mm (pl. 1, 1), is well distinguished by these characters from the specimens from the Gulf of Guinea, which the present author was able to ascertain by a re-examination, but others of the Ingolf specimens are rather intermediate. LIEBERKIND also wrote: "Whether the variety can be upheld later, when a greater material from more localities are collected, is difficult to decide now, the more so as the characters of the species seem to be rather inconstant." As a further justification for the erection of the variety *groenlandica,* LIEBERKIND refers to the "wide separation" of the two localities, the Gulf of Guinea and the Davis Strait. – With regard to the fauna of the ocean bed below 2500 m, these two localities, however, are really not widely separated.

The Galathea material:

Specimens referable to *Styracaster chuni* were collected in four dredgings, two in the eastern tropical Atlantic, near the type-locality and off Angola respectively, and two in the South Pacific, in the Kermadec Trench north of New Zealand.

St. 52: 1°42′N, 7°51′W, 2550 m, muddy clay. ca. 3°C. 6 specimens.

St. 99: 8°40′S, 11°10′E, 2690 m, yellowish clay, 3.9°C. 7 specimens.

St. 663: 36°31′S, 178°38′W, 4410 m, 1.2°C., brown, sandy clay. 2 specimens.

St. 664: 36°34′S, 178°57′W, 4510-4570 m, 1.1°C., brown sandy clay. 5 specimens.

The Atlantic material (figs. 3, 20*a-h*):

The present Atlantic specimens of *Styracaster chuni* are all fairly large ones. Those from st. 52 have R/r 39/12, 41/14, 43/14, 44/13, 44/14, and 49/15 mm respectively, and three of those from st. 99 have R/r 56/18, 60/19, and 64/21 mm respectively. (The remaining four specimens from st. 99 are of about the same size, but have to be left out of consideration, since they are present in the form of loose skeletons only, probably having been dried without previous preservation).

The number of superomarginals in these specimens are 11-12, 12-13, 13-14, 12-13, 12-13, 15, 13-14, 17-19 (by R 60 mm), and 14 (by R 64 mm). The joining of the opposite superomarginals of either side of the arms takes place at the fourth, fifth or sixth plates, varying independently of the size of the specimens. The superomarginals of the arms are subquadrate, and usually they stand opposite each others, but any degree of alternation may be found in their arrangement, and similarly the inferomarginals of the arms may alternate to a varying degree with the superomarginals. The inferomarginals in the arms are about half as high as the accompanying superomarginals. All the marginals are rather granulated.

The number of dorsal spines to each arm is usually 2 or 3, but there may be as many as 6 spines. One of the specimens from st. 52, with R/r 44/13 mm, has only a single dorsal spine on each arm, while another from the same population, R/r 49/15 mm, has 6 spines on two arms and 5 spines on the three other arms. There is always a spine developed on one of the plates of the first pair of joining superomarginals, and the other spines – if such are present – are usually placed on the proximal half of the arms, but they may also be found scattered along the whole length of the arms. Normally, only one of the plates in each joining pair of opposites bears a spine, and the spines may then be developed on succeeding pairs of superomarginals, on plates of the same side of the arm, or alternatingly on plates of either side, or the spines may be scattered along the arm, with one or more pairs of naked plates in between. Occasionally both plates in a joining pair of opposites have a spine developed, and these spines are then generally of unequal size, but e. g. the specimen with 5-6 arm spines has proximally on two arms 2 large subequal spines side by side, one to each plate of the first joining pair of superomarginals. Rarely a single superomarginal plate may carry 2 or 3 spines, a large one and 1-2 additional small ones. The dorsal arm spines are fairly robust, conical, pointed, up to about twice as long as the superomarginal plates on which they are borne, and usually slightly curved towards the disk. The proximal spine is the largest, but the other spines of the arms are usually almost just as large. The spine-bearing plates are somewhat enlarged and dorsally protruded so that a conical base for the spine is formed.

The cribriform organs are present in a number of 7 in each interradius in four of the available nine specimens. Two specimens, R/r 39/12 and 44/13 mm,

have only 5 cribriform organs, two others, R/r 56/18 and 64/21 mm, show also only 5 well-developed cribriform organs in each interradius, but, in addition, there may be 1-2 rudimentary ones; and one specimen with R/r 49/15 mm has 9 cribriform organs in each interradius, viz. a series of 7 well-developed ones and a rudimentary one to each side. (The smallest specimen of *Styracaster chuni* which the present author has examined, one from the Ingolf st. 37 with R 19 mm, but not mentioned by LIEBERKIND, had already 7 cribriform organs developed in each interradius).

The number of cribriform organs is individually variable and not merely connected with the age of the specimens, though specimens which originally had 5 or 7 cribriform organs (apparently developed almost simultaneously in the juveniles) with growth may add an additional cribriform organ to one or to both sides of the original series. The cribriform organ is usually of a distinctly papilliform (or better spiniform) structure, but occasionally a cribriform organ may appear rather lamelliform, the papillae being flattened in the vertical plane and fairly broad. The structure of the cribriform organ is thus a taxonomical character which should be used with some caution. Dorsally the cribriform organs are only imperceptibly demarcated from the paxillated disk, whereas they are well marked off ventrally, the series of covering papillae extending from one lateral dorsal corner of the organ downwards almost to the ventral edge of the inferomarginal plate, here bending and continuing close to the margin across the vertical marginal suture to the other side of the organ, and up to its other lateral dorsal corner. Usually the cribriform organs are bordered by straight parallel sides and well separated from each other; their width (number of series of papillae up to about 20) increases with age however, and in some specimens some of the median cribriform organs join their neighbours dorsally and ventrally, leaving free only a narrow streak on the marginals. The outermost rudimentary organs may occasionally be developed either on the superomarginal plates alone or on the inferomarginal plates alone.

The terminal ossicle (fig. 20*h*) is fairly conspicuous. It is distal to the arm end, dorsal to only one rudimentary superomarginal plate, and about as large as the two distal superomarginals together. Typically it is provided with three spines, a very conspicuous large distal terminal one, its length usually exceeding that of the ossicle itself, and a pair of much smaller subterminal ones. Two large distal spines, placed side by side, is found as an abnormality in a single arm, and sometimes there are two pairs of small subterminal spinelets. The large terminal spine constitutes a conspicuous character in the species.

Dorsally, on the main part of the disk, there is a close covering of small paxillae, crowned with 3-7 spinelets, (in different specimens e. g. 3-4, 4-5, or 3-6 paxillar spinelets), and paxillae with as many as 10 spinelets occur scatteredly in some specimens. The paxillae are subequal in height, the shaft in the larger ones about as wide as high, and in the smaller ones about half as wide as high. Centrally on the disk the paxillae are small, and a distinct, though small, apical cone is present in some specimens. At the arm bases, between the marginal plates, there is always a small area without paxillae, but with a pavement of fairly large naked plates, and apparently this is an important specific character. The proximal arm spines, however, may sometimes be placed in such a way that this area with plates becomes rather obscured.

The madreporite is roundish and of a diameter about the length of the superomarginals, quite close to these or separated from them by one or a few series of paxillae. Sometimes the median pair of superomarginals in the interradius with the madreporite is lower than the others, making room for the madreporite which then becomes in part marginal in position. The striae all radiate from an adcentral point, or some of them stretch across in radial direction.

Papulae have not been observed. The gonopores were traced in a specimen from the Ingolf Expedition as a minute papilla at a distance of a single series of paxillae from each of the sutures between the first and second superomarginal plates.

The most proximal adambulacral ossicles are subrhomboid (fig. 20*a*), but in the following ones the furrow margin becomes excavated to give room for the podia, and in the arms the aboral part of the adambulacralia becomes distinctly narrower than the adoral part. The proximal adambulacralia bear on their furrow margin a series of 3, sometimes 4, exceptionally even 5, conical pointed subequal spines. The more distal adambulacralia have 2-3 (perhaps most commonly 2) widely diverging furrow spines placed either close together on the adoral broader part of the ossicle or with the aboral one placed medially on the furrow margin at some distance from the adoral one(s) (fig. 20*b, c*). Scattered

adambulacralia may have 1-2 additional spinelets aborally on the furrow margin of the narrow part of the ossicle (fig. 20*g*). The whole series of furrow spines is joined by a distinct web.

On their surface the adambulacralia bear usually 1-2 (fig. 20*b, c*), but exceptionally 3-4 spinelets or spines, e. g. on some of the more proximal adambulacralia in disk and arms of some of the large specimens (fig. 20*d-f*). If 4 subambulacral spinelets or spines occur, they may be placed two and two side by side near the adoral and aboral margins respectively, but they may also be more irregularly distributed. If there are 2 subambulacral spinelets or spines they are placed with one near the adoral margin, and one at the interradial aboral corner respectively. The aboral subambulacral spinelet or spine seems characteristic of the species. It is usually a well developed spine, and it is absent only in very rare cases.

The ambulacral furrow can be almost completely closed by the ambulacral ossicles meeting over it, but can also be widely opened, and in this case the arms appear as constricted at their bases.

The oral ossicles bear 5-7 spiniform or conical, and sometimes slightly flattened marginal spines, the proximal of which is two or three times as large as the others, and further a number of suboral spinelets, varying from 1 or 2 fairly large ones near the distal margin, or near the suture, to 7 placed in a row along the distal and sutural margin, or more rarely scattered irregularly over the whole surface of the ossicle.

The primary oral ossicle is fairly broad and usually very conspicuous. In the arms the triangular ends of the ambulacral ossicles are distinctly seen wedged in dorsally between the adambulacralia (fig. 3*p*).

The ventrolateral plates are naked in all the specimens. They are transversely elongate, the proximal ones in general much larger than the distal ones, and arranged in tangential and in usually indistinct radial series. The number of plates in the proximal tangential row varies from 1 to 6. Two radial series of plates may correspond with a marginal plate, but the number of distal plates corresponding with a marginal one may also be 3 or 4.

A thick integument covers the ventral and also the dorsal side in several specimens.

The Pacific material (fig. 20*i-p*. Pl. X 3-5):

The seven specimens of *Styracaster chuni* available from two dredgings in the Kermadec Trench have R/r 36/12, 38/13, 50/17, 51/18, 54/14, and 55/17 mm. The two largest specimens are from st. 663, the other four from st. 664, and further from this station there is a fifth, fragmentary specimen of the same size-group. The ratio R/r ranges from a little less than 3 to almost 4 (this latter, however, in a specimen with an empty stomach, and with the disk markedly excave interradially).

The superomarginal plates number 17, 15, 18, 15, 18, and 17 respectively, and join their opposites from plates nos. 4-6. The superomarginals are subquadrate, and the inferomarginals in the arms are about half as high as their superomarginal companions. In the arms the superomarginals are exactly opposite each other or alternate more or less regularly, as described for the Atlantic material, and they may then be pentagonal in shape, even hexagonal if also alternating with the adjoining inferomarginals. The surface of the marginal plates is rather smooth as was the case with the specimens from the Davis Strait described by LIEBERKIND.

The number of arm spines in these specimens varies in the same way as it did in the Atlantic ones. The two larger specimens (st. 663) have 3-4 dorsal spines on each arm (only on a single arm 2); the specimen with R/r 50/17 mm has 4-5 arm spines, that with R/r 36/12 mm has 2-3 arm spines, whereas the other three specimens from st. 664 have only 1-2 spines on each arm, one of them even only a single spine on four of the arms. In two of the specimens with only 1-2 arm spines (R/r 38/13 and 51/18 mm) the proximal (and perhaps only) spine is placed not on one of the plates of the first pair of joining superomarginals, as is the case in all other specimens of *Styracaster chuni* known, but on plates of the second and the third joining pairs respectively. The superomarginal plates in these specimens join their opposites from nos. 5 and 4 respectively, and it is always the sixth plate which bears the most proximal spine. The arm spines in the specimens from the Kermadec Trench on the average appear slightly smaller and more slender than those in the Atlantic specimens known. They are likewise curved slightly in the direction towards the disk.

The cribriform organs are present in a number of 5 to each interradius in three specimens with R/r 38/13, 51/18, and 54/17 mm; in the others they number 6-7, but the additional organs to one or to either sides of the 5 median ones are usually rudimentary. The structure of the cribriform organs is papilliform or rather sublamelliform, the papillae being dis-

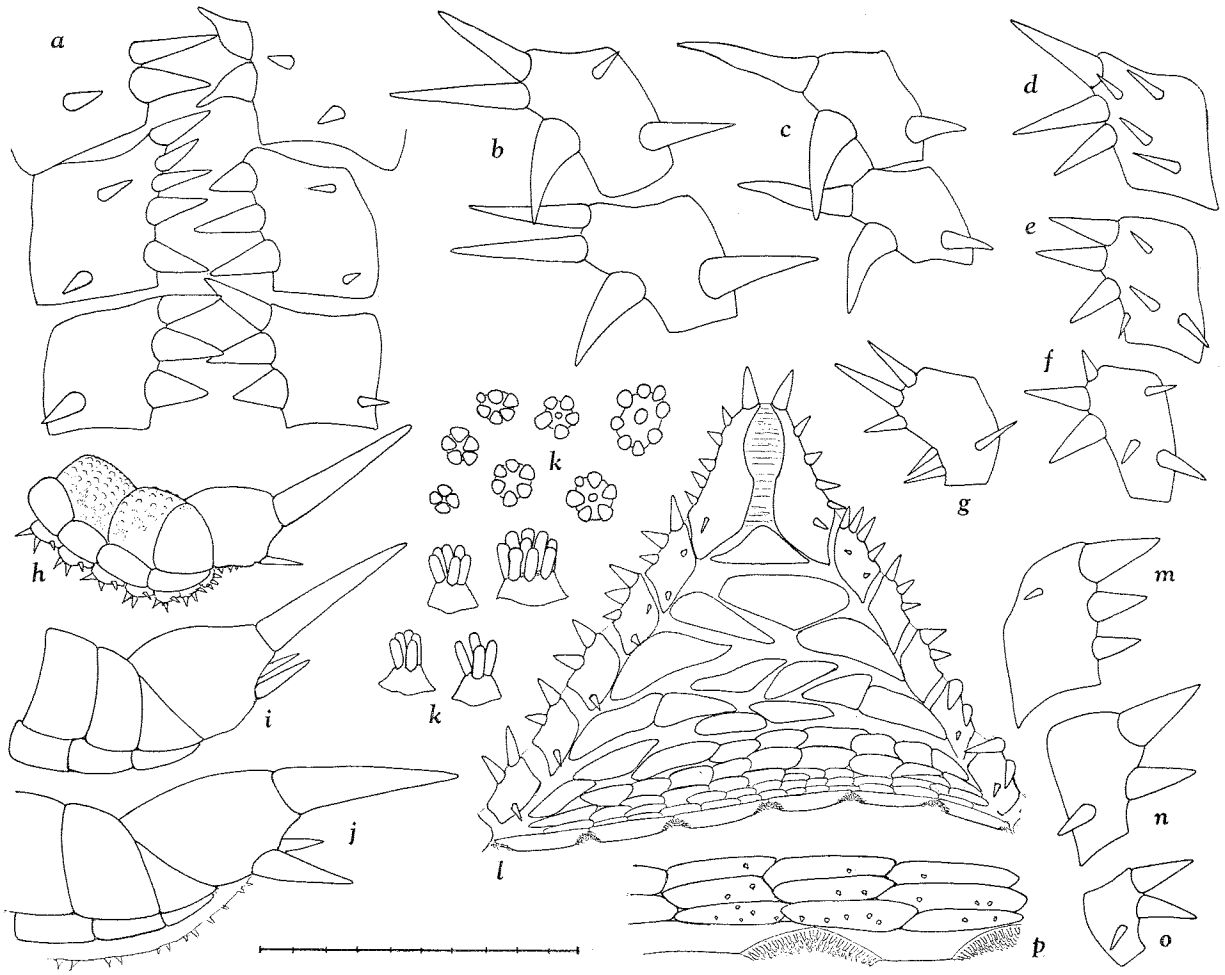

Fig. 20. *Styracaster chuni*. a-c) St. 99, medium-sized specimen, R ab. 60 mm; a, distal part of oral ossicles and adambulacralia nos. 1-2; b-c, adambulacralia nos. 6-7 and 10-11 respectively. d-f) St. 99, another medium-sized specimen, R ab. 60 mm, adambulacralia nos. 5, 10, and 14 respectively. g) St. 99, a third medium-sized specimen, R ab. 60 mm, adambulacral ossicle no. 17. h) St. 99, R/r 60/19 mm, the granulated surface is indicated on some of the marginalia. i) St. 664, R/r 36/12 mm. j) St. 663, R/r 55/19 mm. k-o) St. 664, R/r 50/17 mm; m,n,o, adambulacralia nos. 1 and 5, and one from the median part of the arm. p) St. 664, R/r 51/18 mm, part of ventral area mid-interradially.
Scale in 1: 10 mm, in a-j and m-p: 5 mm, in k: 2.5 mm.

tinctly flattened in the vertical plane. In one specimen the supero- and inferomarginal plates in some of the interradii do not quite correspond with each other, which results in some irregularity in the arrangement of the cribriform organs.

The terminal ossicles are, as is characteristic also of the Atlantic specimens, fairly conspicuous, with a large distal terminal spine and a pair of usually much smaller subterminal ones (fig. 20*i, j*).

The paxillae, covering the main part of the disk, carry generally 4-7, but occasionally 8 or 9 spinelets (fig. 20*k*). The paxillar shafts are about as wide as high, and the spinelets are about as long as the height of the shafts. The central area with crowded small paxillae, is slightly elevated in some specimens. At the arm bases, for an area corresponding to about two marginal plates, no paxillae are developed, and instead there is a pavement of plates of a somewhat varying size (pl. X 5), but distinctly larger than the paxillar bases, and sometimes so crowded that they partly cover each other. As noted in the description of the Atlantic specimens, this pavement of plates in the arm bases seems an important specific character.

The madreporic body is circular, close to the marginals or separated from these by two rows of paxillae. The striae may stretch across in radial direction or may all radiate from an adcentral point.

The more proximal adambulacral ossicles of the disk area are provided with a furrow series of 3-4 spines and bear normally 1-2 adorally placed granules or spinelets on their surface and an abo-

rally placed spinelet (fig. 20*l*). Some ossicles among the first 1-3, may have only the aborally placed subambulacral spinelet developed (fig. 20*m*), and even this may be missing, and the surface of the more proximal adambulacralia completely naked. The more distal adambulacral ossicles have usually only 2 furrow spines, conical, pointed, and placed on the adoral broad part of the ossicle, and invariably a small aborally placed subambulacral spine (fig. 20*n, o*). As mentioned in the discussion of the Atlantic specimens, this aboral subambulacral spine (only sometimes absent on the more proximal adambulacralia) seems to constitute a constant specific character.

The oral ossicles carry 4-6 marginal spines, the proximal of which more or less distinctly larger than the others. Their surface is naked or maybe provided with 1 (-2) spinelets distally (fig. 20*l*).

The ventrolateral plates (fig. 20*l, p*) are arranged in about 7-10 tangential rows. Distally they are small, transversely elongate and closely crowded, overlapping each other, proximally they are larger, often also transversely elongate, but sometimes of any other possible shapes. Often there is only one plate in the first tangential row and only two plates in the second row. The ventrolateral plates are further typically arranged in distinct radial series which correspond two and two with the adjoining marginal plates; but their number may be increased distally in some interradii in which then 3 or maybe 4 plates adjoin each marginal one. The ventrolateral plates in general appear naked as was also the case in all examined Atlantic specimens of *S. chuni*. Two specimens, however, with R/r 38/13 and 51/18 mm, have up to half a dozen granuliform spinelets on the most distal ventrolateral plates (fig. 20*p*), and 1-2 granuliform spinelets on some of the other plates. Also another specimen has single granules on a few of the more proximal plates.

Remarks:

There can be no doubt that these Pacific specimens belong to the species *Styracaster chuni,* hitherto known only from the Atlantic. Their marginal plates appear somewhat more smooth than do those in the specimens from the Gulf of Guinea; but in this respect they are similar to specimens from the Davis Strait. A few of the Pacific specimens examined, have a modestly developed ventrolateral armature of granuliform spinelets, whereas all Atlantic specimens examined, had a naked ventral side. This latter feature, however, applies also to other of the Pacific specimens, and the possession of ventrolateral granules or spinelets thus cannot be considered of any decisive taxonomic importance. In all other characters, the Atlantic and the Pacific specimens examined show an identical variation.

Distribution:

Styracaster chuni is known from six dredgings (fig. 36): four in the Atlantic, in the Davis Strait and the area of the Gulf of Guinea, and two in the South Pacific, in the Kermadec Trench north of New Zealand. Its bathymetrical distribution is from 2550 to 4510-4570 m. It is found at temperatures from 1.1° to 3.9°C. The bottom recorded always is clay. It is a fairly robust species and perhaps there is a connection between its robust appearance and its occurrence on a clay bottom.

Styracaster paucispinus Ludwig, 1907

Ludwig 1907 pp. 315-316.
H. L. Clark 1920 pp. 80-81, pl. 2_{3-4}.

This species was preliminarily described by Ludwig from two specimens collected by the Albatross in the eastern tropical Pacific (st. 4658: 8°30'S, 85°36'W, 4335 m, fine green mud, 1.8°C.). The same material was briefly discussed in 1920 by H. L. Clark, who also published photographs of one of the specimens in dorsal as well as in ventral aspect.

The two specimens have R/r 19/9 and 22/9 mm; 6 and 7 superomarginals (according to the photo joining from no. 5); 1-2 (3?) arm spines; 3 broad cribriform organs; terminal ossicle with 3 spines. Dorsal side with closely crowded small paxillae with 4 (-6-8) spinelets (according to the photo confined to main disk area, whereas there is a pavement of naked plates in arm bases). A small apical cone. (The madreporic body in the photographed specimen roundish, with striae radiating from proximal margin). Adambulacralia, 12-13 in number, with 5 blunt furrow spines (having the appearance of segmental papillae and covering a distinct segmental pit, - according to the photo and to Clark's reference to a "marked depression or shallow furrow on the ventral surface ... from the inner adoral corner of the plates, where it is deepest, to the outer aboral corner, where it flattens out entirely"). No subambulacral armature. Oralia with 7 marginal spines, proximal one the largest, and a suboral spinelet near the suture. Ventrolateral plates with spaced granuliform spinelets (according to Clark, however, apparently wanting in one of the specimens).

LUDWIG did not discuss the possible relationships of his *S. paucispinus,* but H. L. CLARK made some considerations thereupon, comparing the species to *armatus, spinosus,* and *edwardsi,* on account of their number of cribriform organs, but noting that it differs from these in the shortness of the arms and correspondingly small number of arm spines. (LUDWIG gave the number of arm spines as 2-3, which, however, would hardly agree with the number of superomarginals stated, and H. L. CLARK also found only 1-2 arm spines, when he re-examined the specimens. But in counting the superomarginals LUDWIG may have neglected possible rudimentary ones below the terminal ossicle).

An important character, missed by both LUDWIG and CLARK, is the armature of naked plates at the arm bases, which appears from the photo. This characteristic, combined with an armature of fairly well developed paxillae on the main part of the disk, these two specimens share only with LUDWIG's *Styracaster chuni.* The ratio R/r, and further the low number of cribriform organs and the paucispine condition of the arms, agree also well with young equal-sized specimens of *S. chuni.* What distinguishes *S. paucispinus* from *S. chuni* is primarily the appearance of the adambulacral armature, with the furrow spines modified as segmental papillae over a distinct segmental pit. Propably, however, this may not be a constant character (considering the variability of the adambulacral armature in *S. horridus* and *Eremicaster crassus* e. g.), and in that case a distinguishing character may perhaps be found in the presence of an aboral subambulacral spinelet in *S. chuni,* whereas in *S. paucispinus* the aboral subambulacral surface appears to be naked.

The two specimens known of *S. paucispinus* are possibly young ones (if the size reached by other species of *Styracaster* is considered), and though they apparently have attained the adult characters, at least in the main, larger specimens, besides a larger number of arm spines and perhaps of cribriform organs, may show a better developed suboral armature and perhaps also have a subambulacral armature on the more proximal ossicles.

Styracaster robustus Koehler, 1908

KOEHLER 1907*b* p. 144 (nom. nud.), 1908 pp. 560-561 (224-225), pl. 4_{44-45}.
WILTON 1908 pl. 13 fig. 39.

KOEHLER described this species on the basis of a single specimen collected by the Scotia Expedition in the Atlantic sector of the Antarctic (51°07'S, 9°31'W, 3846 m, diatom ooze). It has R/r 45/15 mm; 17 superomarginal plates, all higher than long, joining from plates no. 7; 2 conical pointed arm spines, on 7th and 9th pair of superomarginals, the larger proximal one slightly curved towards the disk; inferomarginals of arms apparently about half as high as superomarginals; 11 cribriform organs; terminal ossicle fairly inconspicuous, with a large distal terminal spine and a pair of smaller subterminal ones. Dorsal side (including arm bases, according to the photographs published by WILTON) with numerous close-set paxillae with 3-4 (5) granuliform spinelets. A conspicuous round madreporite. Adambulacralia with 4-5 furrow spines and some granules on their surface. Oralia with 8-9 marginal spines, proximal two, especially the first, enlarged, the others subequal to the adambulacral spines, and with several irregular rows of suboral granules. Ventrolateral area covered with a thick integument with granules.

The type-specimen of *S. robustus* evidently has an empty stomach, and the interradii consequently unusually excave, and probably the radius of the disk would be half the arm length if the stomach was full. The species may be grouped together with *S. chuni* and *S. paucispinus,* which have also relatively short arms. It is easily distinguished from these, however, by the uniform covering with paxillae over the whole dorsal area inclusive of the arm bases, and also by its different oral and adambulacral armature.

Styracaster armatus Sladen, 1883
Fig. 21

SLADEN 1883 pp. 232-234; 1889 pp. 153-154, pls. 24_{1-4}, 28_{1-4}.
WOOD-MASON & ALCOCK 1891*b* p. 434; ALCOCK 1893 p. 86.

SLADEN described this species on the basis of a single specimen dredged by the Challenger in the mid-Pacific near the Caroline Islands (st. 224: 7°45'N, 144°20'E, 3384 m, globigerina ooze, 1.9°C.). WOOD-MASON & ALCOCK have later recorded the species as taken by the Investigator in two dredgings in the Bay of Bengal, in depths of 3365 and 3519 m respectively, and on a bottom of globigerina ooze.

The type-specimen has R/r 38/11 mm; 9 superomarginals, considerably longer than high, joining from plates no. 4; a continuous row of 5 arm spines;

inferomarginals lower than superomarginals, about three times as long as high; 3 broad papilliform cribriform organs. Terminal ossicle fairly inconspicuous, with 3 spines. Dorsal side with a thick integument with closely crowded minute imperfect pseudopaxillae and simple spinelets, and with naked spaces at arm bases. A faint apical cone. (Madreporic body according to figure round and with striae radiating from its center). Adambulacralia elongate (vertebra-shaped), with 3 pointed slightly compressed furrow spines on adoral half, and a single small conical subambulacral spine near interradial adoral corner. Oralia large, markedly coulter-shaped, only joining their opposites proximally, being widely separated also medially, where the primary oral ossicle is well exposed; each oralia with 5-6 marginal spines, proximal one not much larger than lateral ones, and with a few spinelets on distal surface. Ventrolateral area with naked squamous plates arranged in tangential and radiating series.

The Galathea specimen:

St. 280: 1°56′N, 77°05′W, 4350 m, 1.3°C., globigerina ooze. 1 specimen.

This specimen, taken S. W. of Ceylon, agrees well with the type-specimen described by SLADEN, showing only negligible variations in some characters. It has R/r 39/13 mm, and is thus of about the same size as the type; and it is clearly adult. (As noted above, p. 92, the present author in 1951 ventured the opinion that SLADEN's *S. armatus* might be a juvenile specimen).

The superomarginal plates number 11-12 in the two arms preserved, and join their opposites from plates no. 4. (The specimen is very mutilated). The superomarginals of the disk are subquadrate, whereas those of the arms are much lower and rectangular, the proximal ones up to twice as long as high (fig. 21*a*). The inferomarginals of the arms are about half as high as their superomarginal companions and thus about three times as long as high. The surface of the marginal plates is granulated, corresponding to what is shown in SLADEN's fig. 4 pl. 28. The superomarginals of either side of the arms are fairly regularly opposite each other, and also the inferomarginals correspond regularly with the accompanying superomarginals.

Each arm bears a continuous row of 8-9 dorsal spines, gradually diminishing in size towards the tip of the arms (as is shown by the sizes of their basal knobs on the plates). The proximal arm spine is borne on one of the superomarginals of the first joining pair, as typical in *Styracaster,* and the following ones are then developed on successive pairs of joining plates, either alternatingly on either side of the arm, or on successive plates of the same side of the arm. Occasionally the two plates in an opposite pair each has a spine developed, but then one spine is always much smaller than its partner. All arm spines are lost in the specimen except a single proximal one, which is slender straight pointed and may have measured about 9 mm (being 8 mm long with the tip broken). The spine is borne on an about 1 mm high knob or protuberance on the superomarginal plate. The arms are very distinctly laterally compressed due to the ambulacral furrow being completely closed. (The arms in the type-specimen are described as subcylindroid). The compressed arms are about 4 mm high at their base.

There are in each interradius three cribriform organs of a rather sublamelliform structure.

The terminal ossicle is distal to the arm end, fairly inconspicuous, rather globular, and with 3 spines, a distal terminal one and a pair of smaller subterminal ones (fig. 21*b*).

The dorsal area shows the leathery integument mentioned by SLADEN. This covers an armature of small rounded plates, about 1/4 mm in diameter, of which those in the radial areas, extending from the arm bases halfway to the center of the disk, are naked, whereas the others bear 1-2, occasionally 3 spines each (about 0.2 mm long and about one-third as wide), (fig. 21*g, h*). There is a faint central elevation with smaller plates and spinelets. The madreporic body is conspicuous, round, close to the marginals, and with the striae radiating from an adcentral point. Papulae were not observed.

The adambulacral ossicles number 24-25. The proximal ones are subrhomboid, otherwise they are elongate, vertebra-shaped as SLADEN very appropriately describes them, with an excave furrow margin, and in the arms with a convex interradial margin. The proximal 1-2 adambulacralia bear 4 pointed flattened furrow spines of which the adoral one is much larger than the others, and further 1-3 subambulacral spines side by side near the adoral margin (fig. 21*c*). The following adambulacralia bear 3 (-4) furrow spines and 1, exceptionally 2, subambulacral spines adorally, and from about the seventh adambulacral ossicle the armature consists of two diverging conical pointed furrow spines on the adoral part of the margin, and an almost equally large subambulacral spine near the interradial adoral

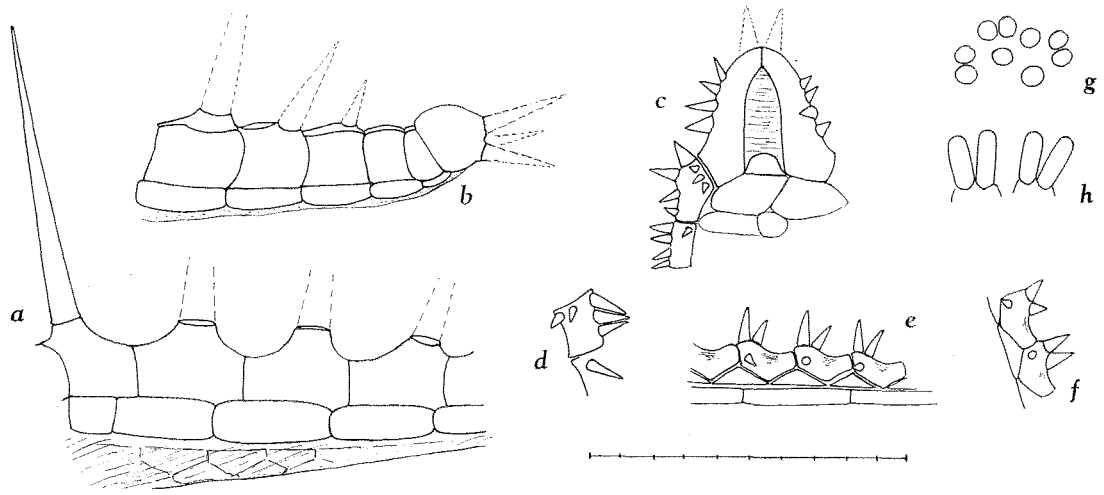

Fig. 21. *Styracaster armatus*. St. 280, R/r 39/13 mm; a, proximal part of arm, showing the superomarginals nos. 4-7; b, distal part of another arm, partly with the granulated surce indicated; c, jaw, with the mouth-spines reconstructed; d, an adambulacral ossicle no. 2; e, adambulacralia nos. 9-11, shown with their surface in the plane of the paper; f, adambulacralia from the median part of another arm; g-h, paxillar spinelets in dorsal view and in lateral view, in four times the usual scale. Scale: 10 mm (in g-h: 2.5 mm).

corner (fig. 21 *e*). The triangular ends of the adambulacral ossicles, observable in the arms dorsally to the adambulacralia, are very wide in this species, actually touching each other in a continuous series.

The oral ossicles of each pair forming a jaw (fig. 21 *c*) only join proximally, and are separated for the greater part of their length by a broad suture, as broad as the semicircular exposed surface of the primary oral ossicle. This appearance of the oralia is apparently an important taxonomical characteristic of the species. Each oral ossicle has carried a larger spine at its tip (lost in the few oralia preserved, the greater part of the oral area of the specimen having been torn away), and laterally at a small distance from the tip there is a series of 4-5 smaller conical and pointed marginal spines. Medially on their surface the oralia may bear a single suboral spine or up to 3 spinelets.

The ventrolateral plates are arranged in about 10 tangential rows, and in the outer half of the disk area also in radiating series, two of these usually corresponding with a marginal plate. The more distal ventrolateral plates are transversely elongate to subhexagonal and the more proximal ones, as usual, larger and irregularly shaped. SLADEN described the ventrolateral plates as imbricating, but in the present, apparently more expanded specimen this applies only to the plates near the margin. The ventrolateral plates are naked. They are of a very porous structure (as seen when the thin covering integument is rubbed off).

Distribution:

Styracaster armatus is known from four dredgings (fig. 37): one in the western tropical mid-Pacific, near the Caroline Islands, and three in the Indian Ocean in the Bay of Bengal and south of Ceylon. It is taken in depths between 3365 and 4350 m, and always on a bottom of globigerina ooze. The temperatures recorded are 1.3° and 1.9° C.

Styracaster spinosus E. Perrier, 1885

Machairaster pictus n. sp., E. PERRIER 1884 p. 272 (nom. nud.).

Styracaster spinosus n. sp., E. PERRIER 1885*a* p. 886 (nom. nud.); 1885*b* pp. 55-59; 1894 pp. 223-227, pl. $17_{2\,a\text{-}d}$.

Styracaster spinosus, KOEHLER 1909*b*, pp. 39-40.

Styracaster edwardsi n. sp., E. PERRIER 1885*a* p. 886 (nom. nud.); 1885*b* pp. 59-60; 1894 pp. 220-223, pl. $17_{3\,a\text{-}e}$.

E. PERRIER in 1884 mentioned a new form of seastar, *Machairaster pictus*, related to *Porcellanaster*, but distinguished by having keeled arms with spines. In a subsequent paper (1885*b*) he described the form in detail, stating that the genus which it represents is that described as *Styracaster* by SLADEN in 1883, and that the form, which he now (by a lapse?) names by the specific name *spinosus*, stands near SLADEN's *Styracaster armatus*. In the final edition (1894) of this paper some figures are added. (SLADEN in 1889 p. 149 notes that *Machairaster* may perhaps prove to belong to *Styracaster*. Thus he

had not seen PERRIER's paper of 1885 before in 1886 finishing his manuscript on the Challenger sea-stars).

The description of *Styracaster spinosus* was based on two specimens collected by the Talisman near the Azores (st. 131: 38°38'N, 27°26'W, 2995 m, soft white mud). The type-specimen has R/r 27/10 mm; 10 superomarginal plates, joining their opposites from plates no. 4, proximal one higher than long, following ones subquadrangular, and those of arms somewhat longer than high (in about the proportion 3/2); a continuous row of 5 arm spines; 3 cribriform organs; terminal ossicle with 3 spines. Dorsal side with a uniform covering of single spinelets, except for a triangular area at each arm base where no spines are developed; a distinct short apical appendage. Adambulacralia with a concave furrow margin and 3 triangular flat pointed furrow spines, two close together and diverging on the adoral broader part of the ossicle, and an isolated aboral one on the narrower part, further 1-2 conical subambulacral spinelets adorally. Oralia joining their opposites proximally and medially, at the primary oral ossicle, between the two places of contact a broad suture; each ossicle with 5 flattened triangular pointed marginal spines, proximal one the largest, and 3-4 suboral spinelets distally. Ventrolateral plates naked, in about 5 tangential and 8 radial rows. A series of isolated ventrolateral plates extending into arms.

KOEHLER in 1909 adds the records of four specimens of *Styracaster spinosus* from three dredgings of the Princesse Alice in the same area as the type-locality, in the eastern Atlantic near the Azores (st. 527: 38°09'N, 23°17'W, 4020 m; st. 745: 38°05'N, 23°50'W, 3465 m, muddy sand; and st. 753: 39°52'N, 18°01'W, 4360 m, globigerina ooze). These specimens have R/r 42/13, (30-35)/10, (30-35)/8, and 22/10 mm respectively, the first mentioned with 14 and the last mentioned with 11 superomarginals. The largest specimen with 3 pointed furrow spines on the proximal 3-4 adambulacralia, and generally only 2 on the following ones; the smallest specimen with 3 furrow spines for the greater length of the arms. The large specimen with 9, the small one with 5-6 arm spines. All specimens with a distinct apical cone.

PERRIER in 1894 notes that his *Styracaster spinosus* is the Atlantic representative of the Pacific *S. armatus* described by SLADEN, but that it is distinguished from this by the shape of its oralia, and by its shorter superomarginal plates.

Styracaster edwardsi: This was described by E. PERRIER (1885) from a single specimen collected by the Talisman in the eastern Atlantic near the Cape Verde Islands (st. 102: 15°18'N, 22°43'W, 3655 m, grey mud). In all probability, however, it is identical with the species *S. spinosus*. The type of *S. edwardsi* has R/r 36/9 mm; 12 superomarginals, joining their opposites from no. 4, first two higher than long, following ones subquadrangular; a continuous row of 7-8 arm spines; 3 cribriform organs. Terminal ossicle elliptical, fairly conspicuous, with 4 spines, a larger distal terminal one, a pair of smaller subterminal ones, and a small median one dorsally. Disk with numerous blunt spinelets, each on its own small plate, but a triangular area at arm bases with naked plates. Madreporic body roundish, with striae radiating from the center. A small apical cone. Adambulacralia with 3 furrow spines, two close together adorally and one isolated aborally; and 1 (on the proximal ossicle 2) subambulacral spine(s) adorally. Oralia in contact with their opposites proximally and medially, with 5 marginal spines, and 4 suboral ones distally. Ventrolateral plates naked, transversely elongate, in about 10 tangential and 14 radial rows. A series of oblong ventrolateral plates extending in arms to marginals no. 6.

PERRIER (1894) notes that his species *Styracaster edwardsi* is close to *S. armatus* and *S. spinosus,* but has longer arms. The length of the arms in relation to the diameter of the disk, however, is usually a rather poor taxonomic character, and neither the different number of terminal spines in *S. spinosus* and *S. edwardsi,* nor that of the superomarginals and the arm spines are of any taxonomical importance. The flattened furrow spines are pointed in *S. spinosus* but blunt in *S. edwardsi,* but as is known from other species, also this may vary individually. The shape of the oral ossicles is the same in *S. spinosus* as in the former form. Thus the conclusion must be that PERRIER's *S. edwardsi* cannot be kept specifically distinct from his *S. spinosus. S. armatus,* as noted above, is distinguished from *S. edwardsi,* and thus also from *S. spinosus,* by having the two oralia of a jaw widely separate also medially.

KOEHLER in 1909 p. 38 writes that he has re-examined the specimens of *S. edwardsi* and *S. spinosus* with the possibility in mind that they might be juveniles of his *S. elongatus,* which he, however, found was not the case. The present author in a paper of 1951, however, did not want to exclude the possibility that *S. spinosus* and *S. edwardsi* were juvenile *S. elongatus,* but the range of variation observed

in the different species of *Styracaster* during the study of the Galathea material has confirmed KOEHLER's view.

Distribution:

Styracaster spinosus (inclusive of *S. edwardsi*) is known from five dredgings in the western Atlantic (fig. 37), near the Azores and the Cape Verde Islands, in depths from 2995 to 4360 m, and on a bottom of mud, muddy sand or globigerina ooze.

Styracaster clavipes Wood-Mason & Alcock, 1891

WOOD-MASON & ALCOCK 1891*b* p. 434; (ALCOCK 1893 p. 86).

This species was described from a single specimen taken by the Investigator in the Bay of Bengal (st. 117: 11°58'N, 88°52'E, 3197 m, globigerina ooze, 1.7° C.) in this way: "Agrees with *S. armatus* very closely, but differs in the following particulars: – There are five cribriform organs...; the inferomarginals are not much longer than broad; the terminal plate ... is markedly inflated; the median spine of the ... rays are comparatively short and blunt."

From this very brief description it is difficult to form a definite opinion of the specimen. The larger number of cribriform organs in *S. clavipes* is alone of no distinguishing value. Information of the size of the specimen would have been of interest. The different shape of the infero-marginals, in *S. clavipes* "not much longer than broad", in *S. armatus* about three times as long as high, and the difference in the terminal ossicles, in *S. clavipes* "markedly inflated", in *S. armatus* inconspicuous, seem to be more reliable taxonomic characters. These characters are such as also distinguish PERRIER's *S. spinosus* (inclusive of his *S. edwardsi*) from *S. armatus,* and therefore *S. clavipes* may prove to be identical with this latter species.

Styracaster monacanthus Ludwig, 1907

LUDWIG 1907 p. 315.
H. L. CLARK 1920 pp. 79-80, pl. 2_{1-2}.

This species was diagnosed by LUDWIG on the basis of a single specimen from an Albatross dredging in the eastern tropical Pacific (st. 4701: 19°12'S, 102°24'W, 4143 m, dark brown clay, 1.9° C.). The specimen is later mentioned by H. L. CLARK (1920) who also published two photographs of it, from the dorsal and the ventral side respectively.

The unique type has R/r 24/12$^1/_2$ mm, the arms being very short and narrow in relation to the disk; 7 superomarginals, joining from no. 5; a single dorsal spine to each arm, on one of the 5th superomarginal plates; (interradial inferomarginals very low); 7 cribriform organs; terminal ossicle with 3 robust spines. Whole dorsal side of disk fairly closely armed with blunt spinelets, each on its own granula-like plate. No apical cone. Adambulacralia, about 16 in number, with 4 (sometimes 5) furrow spines, (scale-like according to the photo). Oralia with 9 scale-like marginal spines (oral and adambulacral armature thus modified as segmental papillae). (A suboral and subambulacral armature not present, at least not mentioned either by LUDWIG or by CLARK). Ventrolateral area with a pavement of uniformly sized (i. e. all fairly small) subhexagonal squamous naked plates.

H. L. CLARK apparently considered *S. chuni* and *S. paucispinus* the nearest allies of *S. monacanthus,* which, however, may not be true. Among the other species of *Styracaster, S. monacanthus* probably agrees best with those of the *armatus* group, like these having only single spinelets on the dorsal plates (no paxillae), but, according to the photo published, differing by having a uniform armature of spinelets over the whole dorsal side, inclusive of the arm bases, where the species of the *armatus* group show a triangular area with naked plates only. *S. monacanthus,* everything considered, appears very well distinguished from all other known species of *Styracaster* by its general facies, with the very short and narrow arms. (A similar appearance is sometimes shown by individuals of other species in radii where lost arms are regenerating).

Porcellanaster Wyville Thomson, 1877, emend. Fisher, 1905

Type-species: *Porcellanaster cæruleus* Wyville Thomson, 1877.

Syn.: *Caulaster* E. Perrier, 1882 (type-species: *C. pedunculatus* E. Perrier, 1882).
Albatrossia Ludwig, 1905 (type-species: *A. semimarginalis* Ludwig, 1905).
Albatrossaster Ludwig, 1907 (new name to replace *Albatrossia,* erroneously considered invalid).

Diagnosis:

Porcellanasterids with opposite superomarginals separate in whole arm length, and possibly with dorsal spines. Terminal ossicle distal to arm end, not markedly broader than long. A mid-interradial

suture. A single lamelliform cribriform organ. A single proximal mouth-spine, common to both oralia forming a jaw. Pedicellariae sometimes present dorsally on disk, and sometimes formed by the furrow spines.

Description:

The general shape is substellate with the arms rather broad, rounded, and only slightly tapering. The disk is rather gibbous, and of a tumid appearance in well-expanded specimens. Usually there is an apical appendage. Small spiniferous plates are distributed over the central dorsal area to an extent varying with age, but not farther than a line connecting the distal edges of the outermost cribriform organs. The integument of the arm bases and arms includes spaced perforated plates. In the ventrolateral area there is a pavement of plates which sometimes bear spinelets. The jaws are large and prominent and bear a few marginal spines besides the single larger one, standing at the junction of the two oralia. The adambulacralia are elongate and with a protruding adoral part on which the few (2-3) furrow spines are borne. The surface of the oralia and the adambulacralia is as a rule naked.

Remarks:

The generic name *Porcellanaster* was created by WYVILLE THOMSON in 1877, in his popular account on the work of the Challenger Expedition in the Atlantic, for some sea-stars which were dredged off the coast of the United States of America, S. E. of New York, and which were the first representatives of the group of deep-sea sea-stars now known as the Porcellanasteridae. WYVILLE THOMSON intended to report himself on the collection of sea-stars brought back by the Challenger Expedition,[1] but due to illness had to give it up, and PERCY SLADEN was entrusted with the work. In the Challenger report SLADEN (1883, 1889) then described a total of six species of the genus *Porcellanaster,* inclusive of the *P. cæruleus* named by WYVILLE THOMSON. Later authors have added to this number, so that now altogether 20 different species or nominal species (inclusive of subspecies) have been mentioned in or referred to the genus, though some of them originally classified under other generic names (*Caulaster, Albatrossia* (= *Albatrossaster*), and *Eremicaster*). The species or forms on which the genera *Caulaster* and *Albatrossia* were based by their authors (PERRIER and LUDWIG) thus by later revisors are considered juvenile stages of *Porcellanaster. Albatrossaster* was merely a new name created by LUDWIG to replace *Albatrossia,* erroneusly believed invalid (see p. 134). *Eremicaster* was originally erected by FISHER as a subgenus of *Porcellanaster,* but was by LUDWIG raised to the rank of a genus (but given a somewhat different circumscription), and also FISHER himself later considered *Eremicaster* (in his original sense) of generic rank.

As will be discussed in the following, the genus *Porcellanaster* in the sense of SLADEN should be separated into the two groups: *Porcellanaster* emend. Fisher, and *Eremicaster* sensu Fisher.

The specific (and subspecific) names used in connection with the generic name of *Porcellanaster* are, listed in their chronological order:

cæruleus Wyville Thomson, 1877
pedunculatus (Caulaster) Perrier, 1882
caulifer Sladen, 1883
tuberosus Sladen, 1883
**crassus* Sladen, 1883
**gracilis* Sladen, 1883
sladeni (Caulaster) Perrier, 1885
inermis Perrier, 1885
granulosus Perrier, 1885
eremicus Sladen, 1889
**pacificus* Ludwig, 1905
**waltharii* Ludwig, 1905
semimarginalis (Albatrossia) Ludwig, 1905
nudus (*Albatrossaster*) Ludwig, 1907
**vicinus* Ludwig, 1907
**inermis, vicinus* var., Ludwig, 1907
dubius (*Caulaster*) Koehler, 1909
richardi (*Albatrossaster*) Koehler, 1909
fragilis Döderlein, 1921
irregularis Lieberkind, 1932

1. WYVILLE THOMSEN in 1877 I p. 380 after having described the North West Atlantic type-specimen of *Porcellanaster cæruleus* notes that "This is a very widely distributed deep-water species. We met with it near Tristan d'Acunha in the Southern Sea, and in the North Pacific." The specimens referred to by WYVILLE THOMSON were, however, described as different species by SLADEN, viz: *Porcellanaster eremicus, P. crassus, P. gracilis,* and *P. tuberosus. P. crassus* and *P. gracilis* are now referred to *Eremicaster;* but, as appears from the following, the present author considers SLADEN's *P. eremicus* and *P. tuberosus* inseparable from *P. cæruleus.*

WYVILLE THOMSON further noted p. 380 that: "There is an allied species of the same genus somewhat more ornate, and of an orange instead of a blue colour in the China Sea". Perhaps this statement refers to the specimen described by SLADEN as *Hyphalaster inermis.* The note (1877 II, p. 267) of "a new species of *Porcellanaster* remarkable for a series of long spines running along the centre of the back of each ray", refers to the species described by SLADEN as *Styracaster horridus.*

All these forms have either one or three cribriform organs in each interradius. Those with only a single cribriform organ represent *Porcellanaster* s. str., and those with three cribriform organs (in the list marked with an asterisk) represent *Eremicaster* sensu Fisher. Also a few other, though not constant characters, may distinguish these two forms. Thus pedicellariae may occur in *Porcellanaster,* but have never been found in *Eremicaster*; and in *Eremicaster* the adambulacral spines may be modified as so-called segmental papillae, which are unknown in *Porcellanaster.*

The following nominal species of *Porcellanaster* s. str. are described from the Atlantic: *cæruleus, pedunculatus, sladeni, inermis, granulosus, eremicus, richardi,* and *irregularis*; from the Indian Ocean: *caulifer, dubius,* and *fragilis*; and from the Pacific: *tuberosus, semimarginalis,* and *nudus.*

Porcellanasterids referable to *Porcellanaster* s. str. were hitherto recorded from 79 dredgings: 66 in the Atlantic, six in the Indian Ocean, besides three in the region of the Malay Archipelago, and four in the Pacific. In the present paper is now added the description of 12 specimens collected by the Galathea Expedition in six dredgings, two of which in the Atlantic, two in the Indian Ocean, and two in the Pacific, and of two specimens available from a dredging by the Pickle of the South African Fishery Investigations.

The present author has had occasion to re-examine a good deal of the previously described specimens of *Porcellanaster,* viz. those collected by the Ingolf, the Thor, the Godthaab, and the Valdivia expeditions, and further he has himself reported on the specimens collected by the Swedish Deep-Sea Expedition, and has thus been able to study a total of 54 specimens of *Porcellanaster* from 17 widespread localities. Only about 25 of the remaining specimens known have been described in more or less detail, whereas the others are merely listed.

Porcellanaster s. str. is an intricate group, and much richer collections than are available at present, will be needed to obtain a clear concept of its taxonomy. The Galathea material includes specimens of all sizes, ranging from juveniles about as small as any hitherto on record, to specimens of the known maximum size (R/r about 36/11 mm) and apparently senescent. Several of the forms described in the literature are represented in the material at hand, and undoubtedly they are for the greater part only different stages of growth of one and the same form (*cæruleus*). Actually the present author has been quite unable to find any characters by which the specimens known of *Porcellanaster* s. str. might be separated with certainty into more species or subspecies, and therefore regards the genus as monotypic. It shows polymorphism, however, (cf. e. g. the description p. 140 of the two specimens dredged by the Pickle); and rather confusing it is that some specimens though they are juveniles in their skeleton, nevertheless seem to be sexually mature (*richardi* and *semimarginalis* e. g.). Perhaps these latter may represent a paedomorphic form of the typical *cæruleus.*

The type-species *P. cæruleus,* preliminarily described by WYVILLE THOMSON in 1877, was given a more exhaustive description by SLADEN in 1883 and 1889. (The original spelling of the specific name, *ceruleus,* was by SLADEN emended to *cæruleus*). Several specimens were available, and SLADEN also made a few notes on the infraspecific variation, but it is only in his remarks, in 1889, under his species *P. eremicus* that a few hints are given as to the changes with growth from the juvenile to the adult stage. LIEBERKIND in 1935, when dealing with the Ingolf specimens, is the only author who has given a more detailed account of the variation within the species, especially with growth during the young stages.

LIEBERKIND also discussed the other forms of *Porcellanaster* described in the course of time from the Atlantic, and re-examined several of them, and his conclusions were that most Atlantic specimens of *Porcellanaster* recorded, belonged to the species *P. cæruleus.* He excepts only E. PERRIER's *P. granulosus*; which exception, however, as discussed in the following, he based on a misinterpretation of one of the anatomical features of the genus. Further LIEBERKIND did not take any final view on KOEHLER's *Albatrossaster richardi,* but if he is right in referring all the other forms to *P. cæruleus, A. richardi* can hardly form an exception. This latter view was also maintained by the present author in 1951 when some specimens of *Porcellanaster* from the Swedish Deep-Sea Expedition, agreeing with KOEHLER's description of *richardi,* were recorded under the name of *cæruleus*, LIEBERKIND, in 1935 in his discussion of the Atlantic records of *Porcellanaster,* did not mention his own *P. irregularis,* described in 1932 on the basis of some specimens from the Gulf of Guinea, but since it is not included in the list of synonyms of *P. cæruleus,* he may still regard it as a distinct form. The characters, however, which should

separate *irregularis* from *cæruleus*, viz. irregularities in the arrangement of the marginal plates, are of no taxonomical value whatsoever.

The specimens of *Porcellanaster* recorded from the Indian Ocean and the Pacific were not discussed by LIEBERKIND, who only noted that KOEHLER's *Caulaster dubius*, and LUDWIG's *Albatrossia semimarginalis* and *A. nudus*, are juveniles and not referable with certainty to species. (As will be discussed in the following, nothing can be found in the descriptions of these three forms to distinguish them with certainty from *P. cæruleus*). The other forms of *Porcellanaster* (from other oceans than the Atlantic) are SLADEN's *P. caulifer* and *P. tuberosus*, and DÖDERLEIN's *P. fragilis* (and nothing is found in the description of these to distinguish them from *P. cæruleus*).

Nec: *Porcellanaster cæruleus*, WOOD-MASON & ALCOCK 1891*b* p. 433 (= *Sidonaster* sp.).

WYVILLE THOMSON's description of *Porcellanaster cæruleus* was based on some specimens dredged by the Challenger S. E. of New York (st. 45: 38°34'N, 72°10'W, 2270 m, blue mud, 2.9°C.), and the generic name he gave the form indicated a feature which has proved to be very characteristic of the whole group to which the form belongs (the Porcellanasteridae), viz. the large marginal plates which "are clear white with somewhat of a porcellanous lustre", and the specific name the colour of the disk "ranging from a pale to a tolerably strong cobalt-blue". (VERRILL 1885 p. 520 states about *Porcellanaster cæruleus* that "Its cærulean color is due only to the bluish mud, with which its large stomach is usually filled, showing through the translucent integument. The real color is buff or pale salmon"). WYVILLE THOMSON rightly pointed out the relationship of *Porcellanaster* with *Ctenodiscus*. He also described correctly what he called the ornament, and which later by SLADEN was named the cribriform organ, but he made a lapse in considering the central apical appendage the excretory opening. (He may have had before him, however, a specimen with the appendage broken, and thus showing an artificial hole simulating an anus).

Later SLADEN (1883, 1889) gave a more detailed description of the species, further recording it from two other neighbouring Challenger dredgings (st. 46: 40°17′N, 66°48′W, 2469 m, blue mud, 2.9°C.; and st. 47: 41°14′N, 65°45′W, 2451 m, blue mud). The type-specimen of *Porcellanaster cæruleus,* according to SLADEN, has R/r 22/10.5 mm; 6-7 subquadrate superomarginals, generally armed with a short conical spinelet dorsally (innermost and penultimate plates naked); 6-7 (-8) inferomarginals, in arms somewhat lower than corresponding superomarginals, rectangular; 1 broad lamelliform cribriform organ; terminal ossicle fairly prominent, slightly tubercular, with proximal margin deeply indented and with 3 spines. Dorsal side of disk centrally and interradially with scattered minute plates, each with a spinelet. An apical appendage. Adambulacral ossicles with 2 pointed spines. A single proximal mouth-spine, common to both ossicles forming a jaw, and 2 small flattened lateral marginal spines to each side. Ventrolateral area with a compact pavement of naked plates, (in 4-5 tangential series and in radiating series three of which correspond in width with a marginal plate).

As type WYVILLE THOMSON has chosen a specimen (the largest one) with all the characteristics of a fully developed *Porcellanaster cæruleus,* but as appears from SLADEN's remarks, many of the other Challenger specimens do not show all these characteristics. The smallest specimen has R/r 8/4 mm, 4 unarmed superomarginals, and 4 (5) inferomarginals; spinelets on disk in definite interradial lines; a large apical appendage; and a complete pavement of plates ventrally. The subquadrate superomarginals are usually slightly longer than high, but in some specimens the proportions are reversed. Some larger specimens may have the superomarginal spines aborted, or absent altogether (or, in order words, rudimentary or not developed at all). Other specimens may bear spines on some of the ventrolateral plates. There may be 3 lateral oral spines (as is seen from fig. 2 pl. 20) and also 3 adambulacral ones.

VERRILL (1885 and 1895) recorded *Porcellanaster cæruleus* as taken in 42 hauls during the Albatross explorations in 1883 and 1884 off N. E. America, from 41°28′N to 37°50′N, at depths mainly from between about 1660 and 2750 m, but reaching 3520 m. He does not describe his material (only noted the colour, cf. p. 126), but he figures a specimen with R/r apparently about 14/6 mm, with 6 superomarginals armed with spines, and with spiniferous ventrolateral plates.

SLADEN (1889 p. 130) in the description of *Porcellanaster* notes that he has observed "that some of the small membrane-invested spinelets on the abactinal area are either cleft or double, and simulate the appearance of the sacculate pedicellariae in *Bathybiaster* ... They are generally situated near the marginal plates, and are usually most numerous in the neighbourhood of the madreporiform body." – This is evidently a reference to the pedicellariae found in some juvenile specimens of *Porcellanaster.*

A number of 32 specimens of *Porcellanaster,* the affinity of which with the species *cæruleus* is beyond doubt, was recorded and described by LIEBERKIND in 1935. Twenty-six of them were collected by the Ingolf in a dredging in the Davis Strait (st. 36: 61°50′N, 56°21′W, 2702 m, 1.5°C.), and in five dredgings in the Irminger Sea southwest of Iceland (st. 10: 64°24′N, 28°50′W, 1484 m, globigerina clay, 3.5°C.; st. 11: 64°34′N, 31°12′W, 2448 m, globigerina clay, 1.6°C.; st. 67: 61°30′N, 22°30′W, 1836 m, transition clay, 3.0°C.; st. 68: 62°06′N, 22°30′W, 1587 m, transition clay, 3.4°C.; and st. 83: 62°25′N, 28°30′W, globigerina clay, 1717 m, 3.5°C.). Four specimens were dredged by the Godthaab in the Davis Strait (st. 180: 62°07′N, 55°00′W, 2750 m, gray clay, 1.9°C.), and two were dredged by the Thor southwest of Ireland (st. 178: 48°04′N, 12°40′W, 1800 m). The largest North Atlantic specimen which LIEBERKIND had at disposal (Ingolf st. 36) had R/r about 13/5.5 mm; it has no superomarginal spines developed, but otherwise it agrees perfectly with the description of the type-specimen of *P. cæruleus.* Several of the other specimens from the same population were considerably smaller than any one mentioned from the Challenger material, and served LIEBERKIND in a survey of the changes in the dorsal skeleton with growth during the juvenile stages.

LIEBERKIND only recorded R/r for some of his specimens, e. g. those collected by the Godthaab which have R/r 6/3, 7/4, 8/5, and 9/5 mm. Other examples are (partly measured by the present author): Ingolf st. 10: 5.5/4 and 6/3 mm; Ingolf st. 36: 2.5/1.5-2, 3/2, 3/2, 3.5/2.5, 4/3, 6/2.5, 6-7/3, and 13/5.5 mm; Ingolf st. 67: 7/3 mm; Ingolf st. 68: 6/3 mm; Ingolf st. 83: about 1.5-2/1.5 mm and six specimens about 6-7/2-3 mm; and Thor st. 178: (5-)6/2.5 and 9/3 mm.

On basis of the description of the Challenger specimens, and of the Ingolf and the Thor specimens (which the present author has been able to reexamine), the following tabular survey is made

Tabular survey of the growth-changes in *Porcellanaster cæruleus*.

Specimen No.	Population	References to figures	R/r in mm	Number of plates			Supero-marginal spines	Ventro-lateral plates	Dorsal embry-onic plates
				supero-marg.	infero-marg.	adam-bulacral.			
I	Ingolf st. 83	–	< 2/?	2	1	7	÷	÷	+
II	Ingolf st. 36	LIEBERKIND, fig. 1 B, pl. 2_2	2.5/1.5-2	2	1	4	÷	÷	+

XII	Challenger	SLADEN, pl. $20A_{1-2}$	ca. 17/8	5-6	5	15	+	+	÷
XIII	Challenger	SLADEN, pl. 20_{1-2}	ca. 18/8	6	7	17	+	+	÷
XIV	Challenger	WYV. THOMSON, figs. 97-98 (Type-specimen)	22/10.5	6-7	6-8	(15-17)	+	+	÷

in order to show how some of the features of *Porcellanaster* change with growth. Half of the specimens listed in the table belong to the same population (Ingolf st. 36), and there should be no doubt as to the specific identity of the other specimens listed with those from this population. (The measurements given of the Challenger specimens are based in part on the published figures).

The information of the variation evident from this tabular survey may be supplemented with the following notes.

The superomarginal plates are rectangular in the very small specimens, and may also be so in specimens with R 13 mm, but in general they are subquadrate in specimens with R about 8 mm or more. They are unarmed in all the specimens described by LIEBERKIND, while in the larger Challenger specimens ($R \geqq 17$ mm) those of the proximal part of the arms each bears a small dorsal spine. (To judge from the figure of an Albatross specimen published by VERRILL in 1885, also somewhat smaller North West Atlantic specimens (R about 14 mm?) may have superomarginal spines).

Cribriform organs are not yet developed in specimen no. II. Specimens nos. I and IV show a rudimentary cribriform organ in the interradius with the madreporite. Specimen no. III shows a rudimentary cribriform organ in all five interradii, and so does specimen no. V. All larger specimens have a well marked cribriform organ in each interradius.

The terminal ossicle is very dominating in the smallest specimens, but becomes relatively more inconspicuous with increasing size of the specimens. Usually there are 3 terminal spines, but some ossicles have the usual distal terminal spine replaced by two close-set ones, side by side, and thus are provided with 4 spines. This is e. g. the case in some terminal ossicles in specimens nos. I and VII. Occasionally a terminal ossicle carries 5 spines, viz. besides the usual 3 spines, an additional pair proximally on the dorsal surface.

The embryonic plating of the dorsal side is well distinct in the smallest specimens, the central area of the disk here being completely paved with large rounded, perforated plates. In specimens nos. V and VI the central embryonic plates are more or less absorbed, whereas there are still remnants on embryonic plates discernible in the arms. In the specimens with R 6-7 mm or larger, no traces of the embryonic plates are to be found any longer, and instead there is developed a dorsal skeleton of scattered small rounded plates, each carrying a single spinelet. These small spine-bearing plates first appear interradially near the margin, and thereafter spread along the interradial lines to the center of the disk. In specimens nos. IX to XI there are thus five distinct interradial bands of spinelets. In the larger specimens the spinelet-bearing plates eventually become distributed over the whole main disk area to a curved line connecting the distal corners of the first superomarginal plates. The dorsal spinelets are clothed in a sheat of skin which may reach considerably beyond their tip.

A few pedicellariae occur dorsally, interradially and centrally, in specimens nos. VI and VII. (Also some of the specimens described by LIEBER-

KIND from the Godthaab st. 180 are provided with a few dorsal pedicellariae, but all the other specimens and also those listed here from the Challenger material are without pedicellariae).

Pedicellariae are in the whole group of Porcellanasteridae known only from the genus *Porcellanaster* s. str. LIEBERKIND in 1935, when recording pedicellariae from three of his juvenile specimens, wrote that they were found earlier in only two other forms: *Caulaster dubius* Koehler and *Albatrossaster* Ludwig. This, however, is not quite correct, since pedicellariae were recorded also by PERRIER from his *Caulaster pedunculatus,* and in the genus *Albatrossaster* (= *Albatrossia*) were recorded only from KOEHLER's *A. richardi,* but not from any of the two Pacific species described by LUDWIG (*nudus* and *semimarginalis*). And, as noted above, p. 127, already SLADEN in 1889 indicated the occurrence of pedicellariae in some of the Challenger specimens of *Porcellanaster cæruleus.* It appears that all specimens hitherto recorded with dorsal pedicellariae are juvenile, and the possession of pedicellariae thus may be a juvenile feature, the pedicellariae perhaps being lost with age.

The adambulacralia bear 2 (rarely 3) spiniform or more or less flattened furrow spines on their protruding adoral part. In specimen no. II the adambulacral armature of two flattened and slightly hollowed close-set subequal spines form a pedicellaria. (The same is the case in a specimen from Ingolf st. 67 with R/r 7/3 mm, and in one from st. 68 with R/r 6/3 mm).

The oral ossicles, besides the conical pointed mouth-spine common to both ossicles forming a jaw, bear 2 (rarely 3) lateral spines, spiniform and more or less flattened. (The lateral oral spines in some cases may form pedicellariae as the adambulacral ones, and quite exceptionally they may tend to appear as segmental papillae, cf. pp. 140 and 142).

The ventrolateral area in the small specimens is usually provided only with an integument devoid of any skeleton so that the calcified stone-canal shines distinctly through. In the smallest specimens the inferomarginal skeleton lies close to the adambulacral and oral ossicles. In specimens with R about 8 mm and larger ones there is generally ventrolaterally a complete pavement of close-set polygonal (subhexagonal) plates. Also smaller specimens, however, may sometimes be provided with ventrolateral plates, thus e. g. specimen no. III in which two fairly large plates fill out the whole ventrolateral area in the interradius with the madreporite, (the other interradii being still without any skeleton). Specimens as large as R 9 mm may have only a rudimentary ventrolateral skeleton, in specimen no. X e. g. consisting of two minute plates in each interradius, one to each side of the interradial midline (cf. fig. 4 in LIEBERKIND 1935), and all provided with a single spinelet. (The ventrolateral plates are otherwise generally naked in the Ingolf material; only one other specimen, st. 67 R/r 7/3 mm, has also some ventrolateral spinelets). The occurrence of ventrolateral spines is not correlated with the size of the specimens. Ventrolateral spines are recorded from specimens in the Challenger material, but all the large specimens figured are devoid thereof.

In the following discussion of the specimens of *Porcellanaster* described in the literature, the adult ones, for the sake of convenience, are treated first.

Porcellanaster inermis was created by E. PERRIER (1885, 1894) to receive four specimens dredged by the Talisman near the Azores and near the Cape Verde Islands respectively (st. 131: 38°38'N, 27°26'W, 2995 m, soft white mud; and st. 101: 16°38'N, 20°44'W, 3200 m, grey mud). R/r are 11/7 mm in one specimen. The number of superomarginals is 5 in three specimens and 4 in the fourth, and there are 6 and 5 inferomarginals respectively. The superomarginals are subquadrate, all unarmed in three specimens, but nos. 3 and 4 with a small dorsal spine in the fourth. Cribriform organs with 12-14 lamellae. Terminal ossicles with 3 spines. Main area of disk with minute plates with single spinelets. A distinct apical appendage. Adambulacralia with 2 diverging spines. Oralia with 3 lateral spines besides the mouth-spine. Ventrolateral area with a pavement of naked plates in up to 6 tangential rows.

LIEBERKIND (1935) re-examined one of the original specimens, and declared *inermis* to be identical with *cæruleus.* The specimens named *P. inermis* agree with the Ingolf specimen no. XI in the table p. 128.

Porcellanaster granulosus was erected by E. PERRIER (1885, 1894) on the basis of five specimens from three Talisman dredgings near the Cape Verdes (st. 96: 19°18'N, 20°21'W, 2330-2320 m, greenish mud; st. 97: 19°12'N, 20°17'W, 2324 m, greenish grey mud; and st. 101: 16°38'N, 20°44'W, 3200 m, grey mud). The type-specimen has R/r 24/7 mm and 9 subquadrate superomarginals, another one has R

about 20 mm and 8 superomarginals, and also the others are of similar size. All superomarginals, except the first and the last one, with a dorsal spine. Terminal ossicle with 3 spines. Main disk area with a uniform armature of minute plates with single spinelets. Distinct apical appendage. Adambulacralia with 2 flattened pointed spines. Oralia with 2-3 lateral spines besides the mouth-spine. Ventrolateral area with a pavement of naked plates in about 4 tangential rows.

LIEBERKIND (1935 p. 11), after having re-examined one of the original specimens of *Porcellanaster granulosus,* concluded that the form apparently represented a species different from *P. cæruleus:* "being distinguished by a greater number of marginals, a more developed dorsal skeleton, smaller and more numerous ventrolateral plates, and the adambulacral plates in the distal corner cut obliquely, and the lacking piece replaced by a separate triangular plate". With regard to this last feature LIEBERKIND writes: "This character was to be found on each plate, and presuming that a thorough investigation will prove its presence in the other specimens too, this character must be considered so peculiar that the species may be maintained." – These "peculiar triangular plates" noted by LIEBERKIND must, however, be the ends of the adambulacral ossicles (see p. 44), and so nothing is left to distinguish *granulosus* from *cæruleus,* a fact which escaped the present author's attention when in 1951 he reported on the porcellanasterids of the Swedish Deep-Sea Expedition, and in agreement with LIEBERKIND excepted *P. granulosus* from the synonyms of *P. cæruleus.* Actually the specimens recorded under the name of *granulosus* agree perfectly with the type-specimen of *cæruleus* listed as no. XV in the table p. 128.

Porcellanaster irregularis was described by LIEBERKIND (1932) on the basis of three large specimens dredged by the Valdivia off Liberia (st. 63: 2°56′N, 8°04′E, 2492 m, 2.6° C.). LIEBERKIND gave the dimensions of the type-specimen as R/r 33/11 mm (the present author by a re-examination of the specimen found the oral opening very widened, so that 30 mm perhaps would be a truer statement for the length of R). The number of superomarginals is 7 in the type, 8 in another specimen with R about 30 mm, and 6-7 in the third with R 27 mm. The proximal superomarginals are slightly higher than long, otherwise they are subquadrate, or – if subalternating with the inferomarginals – subpentagonal or subhexagonal. Each of the superomarginals nos. 2-5 bears a short pointed spinelet. Terminal ossicles with 3 spines, a distal terminal one, and either a pair of subterminal ones or a pair of proximal dorsal ones, (or, as a re-examination shows, both kinds present and thus 5 spines in all). Disk area with a uniform covering of spaced small perforated plates with single spinelets; in the arms slightly larger naked plates. An apical cone. Adambulacralia with 2 slender spines. Oralia with 2 slender lateral spines besides the proximal mouth-spine (this latter reduplicated on some ossicles). Ventrolateral area paved with naked plates. (About 6 ventrolateral plates adjoin the first inferomarginal one).

As the primarily distinguishing character for his new species, LIEBERKIND mentions the irregularity in the arrangement of the marginal plates. This character, however, cannot be considered of any taxonomic value, representing merely an individual variation. Another character, which according to LIEBERKIND should distinguish *P. irregularis* from *P. cæruleus,* viz. a denser dorsal armature, neither is of any specific value, but is simply what could be expected in specimens of *cæruleus* almost one-third larger than any other specimens known previously. A few similarly large specimens from the Galathea Expedition will be described in the following.

All three additional forms of *Porcellanaster* described from the Atlantic on adult specimens (*inermis, granulosus,* and *irregularis*) are thus without reservation to be referred to the type-species *cæruleus.* Before entering on the discussion of the remaining species described from the Atlantic, all on the basis of juvenile specimens (*pedunculatus, sladeni, eremicus,* and *richardi*), it seems most convenient, however, to discuss the forms described on adult specimens from the Indian Ocean and the Pacific (*caulifer, tuberosus,* and *fragilis*).

Porcellanaster caulifer was described by SLADEN (1883, 1889) on the basis of a single specimen collected by the Challenger in the Arafura Sea in the Malay Archipelago (st. 191: 5°41′S, 134°05′E, 1463 m, green mud, 4.2° C.). It has R/r 21/6.5 mm; 7 superomarginals; slightly longer than high, each armed with a dorsal spine. Terminal ossicles with 3-5 spines (a proximal pair sometimes present). Main area of disk with an armature of slightly clavate spinelets; scattered papulae; a large apical appendage. Adambulacralia (14-15 according to the figure) with 2 spines. Oralia with 3 lateral spines besides the mouth-spine. Ventrolateral area with naked plates.

KOEHLER (1909*a*) recorded under the name of *caulifer* about a dozen specimens of *Porcellanaster,* collected by the Investigator in four dredgings in the Indian Ocean, in the Arabian Sea (Gulf of Oman), south of Ceylon, and in the Bay of Bengal, respectively (st. 299: 23°43′N, 58°52′E, 2376 m, soft green mud, 2.2°C.; st. 300: 24°16′N, 60°26′E, 2130-2515 m, green mud, 1.8°C.; st. 316: 5°44′N, 80°06′E, 2744 m, green mud, 1.7°C.; and st. 111: 12°50′N, 90°52′E, 3044 m, globigerina ooze, 1.9°C.). (The specimen from st. 111 may have been one of those recorded as *Porcellanaster* prox. *cæruleus* by WOOD-MASON & ALCOCK 1891*b*, p. 434). KOEHLER's material comprised a few juvenile specimens, some with R 12-16 mm, and one with R about 22 mm. He does not give any description, apart from mentioning that some specimens, especially among the large ones, carry spines on the ventrolateral plates. He notes that this cannot be considered a specific character however, since SLADEN has recorded the occurrence of ventrolateral spines also in some specimens of *cæruleus* (KOEHLER by an error writes *caulifer*). The Galathea material includes some specimens of *Porcellanaster* which closely agree with SLADEN's and KOEHLER's descriptions of *P. caulifer,* and the conclusion drawn from the study of these is that the form cannot be upheld as specifically distinct from *cæruleus*. SLADEN pointed out as distinguishing characters e. g. the long apical appendage (but the length of this is of no taxonomic value at all) and the clavate spinelets on the disk (but slightly clavate spinelets on the disk is found also in some Atlantic specimens of *Porcellanaster*).

Porcellanaster tuberosus was described by SLADEN (1883, 1889) from a single specimen collected by the Challenger off southern Japan (st. 237: 34°37′N, 140°32′E, 3429 m, blue mud, 1.8°C.). SLADEN gives R/r as 18.5/6 mm (but judging from the drawings in the Challenger report, 15 mm would perhaps be a truer figure of R, the specimen being very much extended by a full stomach and having the arms curved over the disk). There are 4 rectangular superomarginal plates, nos. 2 and 3 armed with a short conical dorsal spine; 5 inferomarginals; a conspicuous terminal ossicle with 3 spines. Whole dorsal area of disk with spinelets; a distinct apical appendage. Adambulacralia (12-14 according to the figures) with 2 spines. Oralia with 2 lateral spines besides the proximal mouth-spine. A ventrolateral pavement of naked plates.

The specimen falls in the number of superomarginals in relation to size within the variation to be expected in *P. cæruleus;* and the only difference from the original material of this form to be pointed out, is the rectangular shape of the superomarginals. The present author has not seen any equal-sized North Atlantic specimens of *P. cæruleus* with just as distinctly rectangular superomarginals as in the type-specimen of *P. tuberosus;* but usually their shape is somewhat variable within the populations, and e. g. the type-specimen of *P. caulifer* has also rather rectangular superomarginals. This difference alone, therefore, cannot be considered of any decisive taxonomic importance. In its other characters the type-specimen of *P. tuberosus* is intermediate between the specimens of *P. cæruleus* listed in the table p. 128 as nos. XI and XII respectively.

Porcellanaster fragilis was erected by DÖDERLEIN in 1921 for three specimens collected by the Siboga in two dredgings in the region of the Malay Archipelago (st. 175: 2°38′S, 130°33′E, 1914 m, grey and green mud; and st. 211: 5°41′S, 120°46′E, 1158 m, grey mud). One specimen has R/r 12/4.5 mm and 6 superomarginals, another R/r 18/6 mm and 8 superomarginals. Superomarginals rather subquadrate, and each with a spine; inferomarginals in arms half as high as superomarginals. Dorsally small plates, in disk with single spinelets, in arms naked; distinct apical appendage. Adambulacralia (14 in number by R 18 mm) with 2 spines, distally in the arms only 1. Oralia with 2 lateral spines besides the proximal mouth-spine. Ventrolateral area with a few naked plates.

DÖDERLEIN notes that his new species is near *cæruleus,* but is distinguished – among other things, he says – by the longer arms and more complete spine-armature dorsally. Neither of these characters, which are the only ones which DÖDERLEIN mentions, are of any taxonomic value, however. In the description the only other feature of some interest is that of the adambulacral armature distally in the arms consisting of only a single spine (whereas in all other specimens of *Porcellanaster* known, there seem to be 2 spines, also on the rudimentary adambulacral ossicles below the terminal ossicles), but even if correctly described also this character cannot be sufficient for distinguishing *fragilis* as a separate species. *P. fragilis* may justly be included among the synonyms of *cæruleus*. (What DÖDERLEIN, 1921 p. 15, mentions as "erste Reihe von Ventrolateralplatten", are in fact the ends of the adambulacral ossicles;

and what he, when describing the ventrolateral plates, mentions as "eine unpaare von dreieckiger Gestalt" aborally to the oralia, is of course the ventral surface of the primary oral ossicle).

It will appear from these considerations that not a single one of the six forms of *Porcellanaster* described on adult specimens, is really specifically distinguishable from the type-species *cæruleus*. It remains now to consider the seven forms based on juvenile specimens; and first are discussed the four forms from the Atlantic: *pedunculatus, sladeni, eremicus,* and *richardi*.

Caulaster pedunculatus was erected by E. PERRIER in 1882 for two small sea-stars collected by the Travailleur in two dredgings in the Bay of Biscay north of Spain (1880 st. 10: "au large de Santander", 1960 m; and 1881 st. 4, 43°N, 9°37'W, 2020 m, mud). (The depth of the latter dredging was in 1882 given as 2650 m, in 1885 as 2400-2600 m, and eventually in 1894 as 2020 m, apparently due to a confusion of the trawling no. 4 in 1881 with no. 4 in 1880). The two specimens have R/r 3/2 and 5/3 mm respectively; 3 superomarginals, 3 distinctly lower inferomarginals; narrow cribriform organs. Terminal ossicles conspicuous, with a proximal notch and 3 spines. Dorsal side with embryonic plates, large and distinct in the small specimens, indistinct in the large one, in which there is also a double row of spinelets in each interradial line. A conspicuous apical appendage. Dorsal pedicellariae. Adambulacralia (10 in the large one) with two lanceolate spines. Oralia usually with 2 flattened and pointed lateral spines besides the mouth-spine (judging from the figures and the somewhat obscure text, the armature may vary on the different oralia as is also known in other specimens of *Porcellanaster,* the mouth-spine apparently may be reduplicated, and there may be a third spiniform spine on the proximal lateral corner of the ossicle, or only a single oral spine laterally). Ventrolateral area with a tangential row of plates.

SLADEN in 1883, p. 217, and somewhat more detailed in 1889, pp. 130-131, expressed the opinion that *Caulaster pedunculatus* is a juvenile *Porcellanaster*. PERRIER in 1894, however, maintained his genus *Caulaster,* and described also an additional species, *C. sladeni*. LUDWIG (1907 p. 318) considered *C. pedunculatus* a juvenile *P. cæruleus,* and LIEBERKIND in 1935, after having re-examined one of the original specimens, confirms this view. The smallest specimen will be found rather to agree with the juvenile *cæruleus* no. III in the table p. 128, and the large specimen is intermediate between the specimens nos. VI and VII.

Caulaster sladeni was erected by E. PERRIER (1885*b*, 1894) on the basis of two specimens dredged by the Talisman off Morocco (st. 30: 32°38'N, 12°09'W, 1900-1435 m, sand and mud). R/r 10/5 mm; 4 (-5?) rectangular superomarginals, 4 somewhat lower inferomarginals; cribriform organs with 8-10 lamellae. Conspicuous terminal ossicle with 3 spines. Dorsal side with irregular (double) interradial rows of minute plates with spinelets; no embryonic plates; an apical appendage. Adambulacralia with 2 spines. Oralia with 3 lateral spines besides the proximal mouth-spine (the latter sometimes reduplicated?). Ventrolateral area with a few plates in two tangential rows.

LUDWIG in 1907, p. 318, expressed the opinion that this form was the juvenile *Porcellanaster inermis*. LIEBERKIND in 1935, after having re-examined a couple of the original specimens of *C. sladeni* and *C. inermis*, arrived at the conclusion that the former was a juvenile and the latter a small specimen of *P. cæruleus*. The specimens will be found to agree with the specimens of *P. cæruleus* listed as nos. IX and X in the table p. 128.

PERRIER mentions (1894 p. 210) a pair of small membraneous papillae at the base of the arms of his *Caulaster sladeni* as "peuvent être soit de papilles respiratoires, soit les orifices des organes génitaux". These are the gonad papillae, which are also observable in some of the juvenile specimens of *Porcellanaster* in the Galathea material (cf. fig. 24*c. o*).

Porcellanaster eremicus was erected by SLADEN in 1889 for a single juvenile specimen dredged by the Challenger in the southern Atlantic west of Cape (st. 137: 35°59'S, 1°34'E, 4664 m, red clay, 1.4°C.). R/r 6.5/3.2 mm; 4 rectangular superomarginals, 3 inferomarginals; terminal ossicle fairly conspicuous, with 3 spines. Dorsal side with a plating of large subcircular or oval perforated embryonic plates. Adambulacralia with 2 flattened lanceolate spines. Oralia markedly coulter-shaped, with 2 lateral spines besides the mouth-spine. No ventrolateral plates.

SLADEN notes that the specimen is "at a very early stage of growth" and "appears to be nearly related to *Porcellanaster cæruleus*". He did not really find any characters reliable for distinguishing it from *cæruleus,* the only difference noted being that the arms "are longer more attenuate and thinner

throughout", and when he, nevertheless, recorded the specimen as representing a new species, it was on account of the distance between the Challenger finds of *cæruleus* and of the present specimen, and further since "this course will also facilitate reference".

LUDWIG in 1907, p. 318, states that he considers *eremicus* a juvenile *cæruleus*, and H. L. CLARK in 1923 and LIEBERKIND in 1935 are of the same opinion.

It is evident that *Porcellanaster eremicus* is very closely related to the North-Atlantic *cæruleus*, but it differs slightly from the population from e. g. the Ingolf st. 36 (cf. the table p. 128) in having retained a complete dorsal embryonic plating up to a somewhat larger size. (See further p. 134).

H. L. CLARK in 1923 recorded four juvenile *Porcellanaster cæruleus* (R 7-9 mm) from two dredgings of the "Pieter Faure" in the Cape region (Cape Point N. E. by E. 1/4 E., 40 miles, 1460-1650 m, green mud; and Cape Point N. 83°E., 43 miles, 1650-1830 m, grey mud).

CLARK notes that these specimens "are too young to make their specific identity certain but comparison with somewhat larger specimens of *cæruleus*, taken by the Challenger and the Blake, indicates that they are immature examples of that species". (He also says that "On account of the locality it would be natural to refer these specimens to *P. eremicus* Sladen, but I (CLARK) am myself satisfied that the specimen on which that species is based, is a young *cæruleus*"). A couple of specimens subequal-sized with SLADEN's *eremicus* and H. L. CLARK's *cæruleus* and also from the Cape region, will be described in detail in the following.

Albatrossaster richardi was erected by KOEHLER in 1909*b* for a single specimen dredged in the tropical mid-Atlantic by the Princesse Alice (st. 1173: 12°08'N, 33°33'W, 6035 m), and erroneusly listed under the name of *Hyphalaster parfaiti* by ALBERT in 1902 p. 962, and by RICHARD in 1902 p. 86. (The genus *Albatrossaster* was erected by LUDWIG in 1905, and is discussed below). The specimen has R/r 10/4 mm; 5 rectangular superomarginals, 2-3-4 rudimentary inferomarginals; prominent terminal ossicle with 3 spines. A close pavement of rounded plates dorsally on disk, smaller plates in arms. According to KOEHLER p. 26 the dorsal plates "montrent à leur surface un dessin très régulier et élégant formé par des granules trés fins et aplatis disposés en mosaique". This description, however, to judge from the condition in other juvenile specimens of *Porcellanaster*, must be incorrect, being an erroneous interpretation of the appearance under the lens of the perforated embryonic plates. *A. richardi* further has dorsally some pedicellariae in interradial groups of 4-5, and a long apical appendage. Adambulacralia (13-14 in number) with 2 spines, forming a pedicellaria which can be laid down in a pit on the ossicle. Oralia with 2-3 (the figure shows 1-2) lateral pedicellariae similar to the adambulacral ones. Ventrolateral area with some small spaced plates. (KOEHLER notes that the opposite superomarginals of the fourth pair touch each other distally, and that those of the fifth pair meet each other in their whole length, which, however, must be a matter of contraction).

LIEBERKIND in 1935, p. 16, discussed *Albatrossaster richardi* and concluded that it undoubtedly represented an immature stage of a *Porcellanaster*, as he knew such from the Ingolf collections, but that a richer material of the form from neighbouring localities would be required to decide whether it belonged to *P. cæruleus* or to another species.

In 1951 the present author reported, under the name of *P. cæruleus*, on five small specimens dredged in the mid-Atlantic west of the Cape Verde Islands by the Swedish Deep-Sea Expedition (st. 329: 9°44'N, 26°25'W, 5610-5600 m, calcareous red clay, 2.4°C.). They agreed in all essentials with KOEHLER's *A. richardi*, and it was noted that the developmental stage they represent, corresponds with that of only about one-third as large North Atlantic specimens of *cæruleus*. Further it was suggested that the difference in size in relation to the developmental stage might be caused by a different food supply. This, of course, is a conjecture, and may be entirely unfounded. The size at which the embryonic plating of the dorsal side disappears – besides being subject to some individual variation – may perhaps be variable in different populations, without being influenced in any way by the environmental conditions. It may now be questioned, whether it was correct to go still further than LIEBERKIND, and consider *A. richardi* not merely a juvenile *Porcellanaster* but a juvenile *P. cæruleus*. A more detailed discussion of the specimens than given in 1951 may therefore be appropriate.

The five specimens of *Porcellanaster* from the Swedish Deep-Sea Expedition have R/r 8/3, 8/3, 9/4, 10/5, and 10.5/5 mm. There are 4 (in that with R/r 10/5 mm only 3) unarmed rectangular superomarginal plates, and 1-5 inferomarginal plates, their number being variable in the different arms as was

also the case in the type-specimen of *A. richardi*. The dorsal side of the arms as well as of the disk is paved with small rounded perforated plates (embryonic plates). In the large specimens there are, however, also some spinelets interradially, near the margin. All the specimens are further provided with pedicellariae interradially and mainly near the margin, in a number of up to 10-12 in each interradius. There is a distinct, small apical appendage. The immature stage of the specimens is emphasized by the very small size of the madreporite in relation to the superomarginals. The cribriform organs are in some interradii still rudimentary, consisting of merely two "lamellae", whereas there are e. g. up to 6 lamellae in the cribriform organ in the interradius with the madreporite. The adambulacral ossicles number 11-14, and their armature is modified (like in the original specimen of *A. richardi*) as pedicellariae along the whole length of the arms, except on the most distal rudimentary ossicles. The oralia bear, besides the mouth-spine, 3 flattened lateral spines (instead of the pedicellaria in the type of *richardi*). The ventrolateral area is devoid of any skeleton. (The adambulacral pedicellariae are very peculiar and characteristic, but it is evident from the variation in the Ingolf populations of *Porcellanaster* that they are of no use taxonomically, at least not on the species level).

The dorsal aspect of the present specimens with R 8-10.5 mm, is the same as found in specimens of the Ingolf population with R 3-4 mm, but this apparently considerable gap is bridged by SLADEN's *P. eremicus*, which specimen with R 6.5 mm has a similar complete embryonic plating. Certainly KOEHLER's *richardi*, and the specimens discussed from the Swedish Deep-Sea Expedition, and probably also H. L. CLARK's *cæruleus* from near Cape, belong to the same form as Sladen's *eremicus*. Whether they are simply specifically identical with *cæruleus* is, however, difficult to decide definitely, but it is the most probable. Some specimens collected by the Galathea Expedition, and described below, agree perfectly with this group of *eremicus/richardi*.

Three forms of *Porcellanaster* based on juvenile specimens (*semimarginalis, nudus,* and *dubius*) are described from the Pacific and the Indian Ocean, and will be discussed in the following.

Albatrossia semimarginalis was established by LUDWIG in 1905 for the reception of two small specimens from two dredgings of the Albatross in the eastern tropical Pacific (st. 3362: 5°56'N, 85°11'W, 2149 m, green mud, sand and stone, 2.7°C; and st. 3371: 5°26'N, 86°05'W, 1408 m, globigerina ooze, 3.9°C.). They have R/r 11/5.5 and 9/4 mm respectively; 3 and 2 unarmed superomarginal plates, inferomarginals absent or rudimentary. In each interradius a cribriform organ with up to 20 lamellae. Terminal ossicle prominent, with 3 spines. Dorsal side with interradial bands of spinelets, each on a small perforated plate. An apical appendage, (Apparently no papulae). Adambulacralia (9 and 8 in number) with 2-3 spines. Oralia with 2 lateral spines besides the proximal mouth-spine. Ventrolateral area with spaced naked plates. (LUDWIG's statement: "dass die unteren Randplatten fast oder ganz in Wegfall gekommen sind" is incorrect in so far as the condition of course is the reverse, viz. that they are not yet distinctly developed).

LIEBERKIND in 1935 notes that this form is a juvenile *Porcellanaster,* but that the species it represents is undeterminable on basis of the available material alone. If compared with the specimens of *P. cæruleus* in the Ingolf populations, it is seen that *A. semimarginalis* has a slightly smaller number of superomarginal plates in relation to size than is the case in the Ingolf specimens, which, however, is a vague difference; and at least it appears impossible to distinguish *A. semimarginalis* from the specimens recorded as *eremicus/richardi*. A relatively small number of superomarginals is also found in the full-grown type-specimen of *P. tuberosus* (4 by R 18 mm) and e. g. also in the full-grown specimens of *Porcellanaster* from the Galathea st. 281 (5-6 by R 21-25 mm), which minimizes the significance of the character.

(Incidentally, LUDWIG in one of the specimens found eggs, 0.4 mm in diameter, and thus probably yet unripe, cf. p. 49).

Albatrossaster nudus was described by LUDWIG in 1907 from a single specimen collected by the Albatross in the eastern tropical Pacific (st. 4647: 4°33'S, 87°43'W, 3667 m, globigerina ooze, 1.9°C.), and in 1920 H. L. CLARK mentioned the same specimen and published some photos of it. (*Albatrossaster* was a new name created by LUDWIG in 1907 to replace his *Albatrossia* of 1905, in order to avoid confusion with *Albatrossa* (a bird), but as H. L. CLARK in 1920 notes, such a confusion does not seem probable – and in any case the name *Albatrossia* was not invalidated by the name *Albatrossa*). The type and only specimen known of *Albatrossia nuda* has R/r 7/4.5 mm; 2 unarmed rectangular superomarginals, 2 inferomar-

ginals. Conspicuous terminal ossicle with 3 spines. Dorsal side with spinelets only interradially near the cribriform organs. Adambulacralia (8 in number to judge from the published photo) with 2 flat lanceolate spines, proximal ones apparently forming pedicellariae. Oralia with 2 similar lateral spines, besides the conical mouth-spine. Ventrolateral area paved with naked plates.

LUDWIG considers this specimen specifically distinguished from his *semimarginalis* by the almost complete absence of dorsal spinelets. But this character is merely depending on age, as demonstrated above in the survey of the changes with growth in populations of *Porcellanaster* from the North Atlantic. The specimen surely belongs to the same form as *Albatrossaster semimarginalis,* and the considerations made with regard to those specimens thus apply also to this one.

Caulaster dubius was erected by KOEHLER in 1909*a* for a small specimen dredged by the Investigator in the Bay of Bengal (st. 117: 11°58′N, 88°52′E, 3197 m, globigerina ooze, 1.8°C.) and belonging to the material recorded by WOOD-MASON & ALCOCK 1891*b* p. 434, as "*Porcellanaster* sp. proximate to *P. cæruleus*". It has R/r 5/2.5 mm; 3-4 rectangular superomarginals, and 3 narrower inferomarginals. Terminal ossicle conspicuous, with 3 spines. Dorsal side with spinelets in interradial bands, also 3-6 pedicellariae in each interradius. An apical appendage. Adambulacralia in a number of 8, with (2-)3 flattened spines. Oralia with 2 flat lateral spines (mouth-spine apparently lost in the specimen). Ventrolateral area without any skeleton.

LIEBERKIND in 1935, p. 11, briefly discussed this form, and supported KOEHLER in his view that it could not be the young of *P. caulifer,* "and in all probability neither a younger stage of other well-known forms of the genus *Porcellanaster* occurring in the Indian Ocean". The reasons for this conclusion are curious, however, since the specimen in fact agrees well with equal-sized specimens in North Atlantic populations of *P. cæruleus,* e. g. nos. VII and IX in the table p. 128, and may well be considered belonging to this species. (Incidentally, KOEHLER's reasons for reviving the generic name *Caulaster* are not in accordance with a strict nomenclatorical procedure and are rather vague, the main reason being that he considers the use of this name for the specimen most convenient, as he is not sure that it is a juvenile *Porcellanaster,* though – as he notes – it may well be so).

In the above, references have been made to all records of *Porcellanaster,* or forms belonging to this group, except to those given by WOOD-MASON & ALCOCK (1891*a* and *b*), and by ALCOCK (1893), of specimens collected by the Investigator. WOOD-MASON & ALCOCK thus in 1891*a*, p. 13, recorded from off Goa (st. 105: 1353 m) a small *Porcellanaster* "resembling in all important particulars *P. cæruleus*", and in 1891*b*, p. 433, they recorded a specimen of "*Porcellanaster cæruleus*" from the Andaman Sea (st. 113: 1249 m), and, p. 434, numerous small specimens of a "*Porcellanaster* sp. proximate to *P. cæruleus*" from the Bay of Bengal (st. 111 and st. 117: 3044 and 3197 m). ALCOCK in 1893, p. 86, finally added a record of *P. cæruleus* from the Laccadive Sea (st. 107: 1350 m). KOEHLER in 1909*b*, pp. 33-34, – with regard to these records – notes that, when examining the Investigator material sent to him, he did not find a single specimen belonging to *P. cæruleus*. Three specimens were labelled with that name, and KOEHLER confirms that one of them is a *Porcellanaster,* though too young and too damaged for a definite specific assignment. This specimen was from the Bay of Bengal (st. 111: 12°50′N, 90°52′E, 3044 m, globigerina ooze, 1.9°C.). Another specimen, from st. 117, is the one which KOEHLER described as *Caulaster dubius*. The third one, from st. 105, KOEHLER finds is a *Sidonaster*. It may here be added that in all probability also the specimen from st. 113 was a *Sidonaster,* considering that the bottom temperature at this station was 6°C., which temperature does not agree with the occurrence of a *Porcellanaster* (known temperature range: 1.1° to 4.2°C.), but fits well enough with the occurrence of a *Sidonaster* (known temperature range: 1.8° to 11.3°C.). The specimens from st. 111 are probably the same (in part) which KOEHLER records as *P. caulifer*. The only record of which no further information is available, is that of *P. cæruleus* from the Laccadive Sea (st. 107: 8°23′N, 75°47′E, 1350 m, green mud).

The material of *Porcellanaster:*

Specimens of *Porcellanaster* were collected by the Galathea in six dredgings: two in the Atlantic in the Gulf of Guinea, two in the Indian Ocean south of Ceylon, and two in the South Pacific, southwest of Australia and in the Kermadec Trench north of New Zealand respectively.

St. 52: 1°42′N, 7°51′W, 2550 m, ca. 3°C., muddy clay. 3 specimens.
St. 63: 2°00′N, 9°14′E, 1520 m, 3.8°C., blue clay. 1 specimen.
St. 281: 3°38′N, 78°15′E, 3310 m, 1.8°C., globigerina ooze. 3 specimens.
St. 282: 5°32′N, 78°41′E, 4040 m, 1.5°C., blackish mud. 1 specimen.
St. 574: 38°45′S, 159°39′E, 4670 m, 1.2°C. 1 specimen.
St. 664: 36°34′S, 178°57′W, 4540 m, 1.1°C., brown, sandy clay. 3 specimens.

A couple of specimens of *Porcellanaster* dredged near Cape by the Pickle of the South African Fishery Investigations are also available.

Pickle st. 92: 33°50′S, 17°59′E, 2176 m. 2 specimens.

The specimens from st. 52 in the Gulf of Guinea are equal-sized to, and in all characters closely agree with those from the same region described by LIEBERKIND as *P. irregularis*. They are by the present author considered full-grown (in part senescent) specimens of *P. cæruleus*. The small specimen from st. 63, also in the Gulf of Guinea, corresponds to those from off Morocco described by PERRIER as *Caulaster sladeni,* which are considered juvenile *P. cæruleus*. The specimens from st. 281 south of Ceylon are fairly large ones which correspond to that from the Arafura Sea (Malay Archipelago) described by SLADEN as *P. caulifer,* and to those from south of Ceylon later recorded under the same name by KOEHLER. They are by the present author also considered large specimens of *P. cæruleus*. The juvenile specimen from the neighbouring st. 282 agrees with the juvenile *caulifer* described by KOEHLER, as well as with PERRIER's *sladeni*. The large specimens from sts. 52 and 281 have in preserved state still a faint purplish tint.

The two small specimens from Pickle st. 92 near Cape differ somewhat from each other in general appearance, one of them corresponding to KOEHLER's *Albatrossaster richardi* from the mid-Atlantic, the other to PERRIER's *sladeni*. The single small specimen from st. 574 southwest of Australia and the three small ones from st. 664 in the Kermadec Trench, all correspond to that from the South Atlantic west of Cape, described by SLADEN as *P. eremicus*. The present author is convinced that they too are juvenile *P. cæruleus*.

The specimens from Galathea st. 52, in the Gulf of Guinea. (Fig. 22):

The present three specimens have R/r 30/9, 32/11 and 36/11 mm respectively. The last mentioned is the largest specimen known of *Porcellanaster,* the hitherto largest one on record being LIEBERKIND's *P. irregularis* with R/r up to 33/11 mm (to which form these specimens, as noted, correspond), and the second largest PERRIER's *P. granulosus* with R/r up to 24/7 mm. The number of superomarginals in the present three specimens is 8-9. The largest specimen shows a peculiar abnormality in that the ambulacral furrow and the ambulacral and adambulacral skeleton extend beyond the terminal ossicle (fig. 22*j, m*). The superomarginal plates all without exception are armed with a dorsal erect spine in one specimen, whereas in the other specimens the proximal one or two, and the ultimate and perhaps also the penultimate plates are unarmed. The spines are on the more proximal plates placed on their upper margin, but on the more distal plates the spine may be placed just a little lower. The first and second superomarginals may have their joining corners drawn out into a slight projection. (This is also sometimes the case in LIEBERKIND's material of *P. irregularis*).

The inferomarginal plates may lie exactly below their superomarginal companions for the greater length of the arms, or they may subalternate with these already from the plates nos. 2-3. Distally an irregular arrangement of the inferomarginal plates seems to be the usual. They are here generally shorter than the superomarginals; and as furthermore the distalmost one (or two) is developed earlier than its superomarginal partner, the number of inferomarginals may be up to 13-14. In addition a few supplementary plates may be pushed in here and there between the inferomarginal and superomarginal series. A similar irregularity in the arrangement of the inferomarginal plates was considered the main specific character of LIEBERKIND's *P. irregularis,* but such irregularities appear to be a frequent individual variation in various populations of porcellanasterids, and no taxonomic importance can be attached to the feature.

The cribriform organ comprises up to 26 folds, the supporting skeletal elements forming almost continuous lamellae, whereas the calcareous papillae of the covering rows are distinctly separate.

The armature of the terminal ossicles varies somewhat. In the smaller specimen there are 5 spines, a conical distal terminal one, a pair of

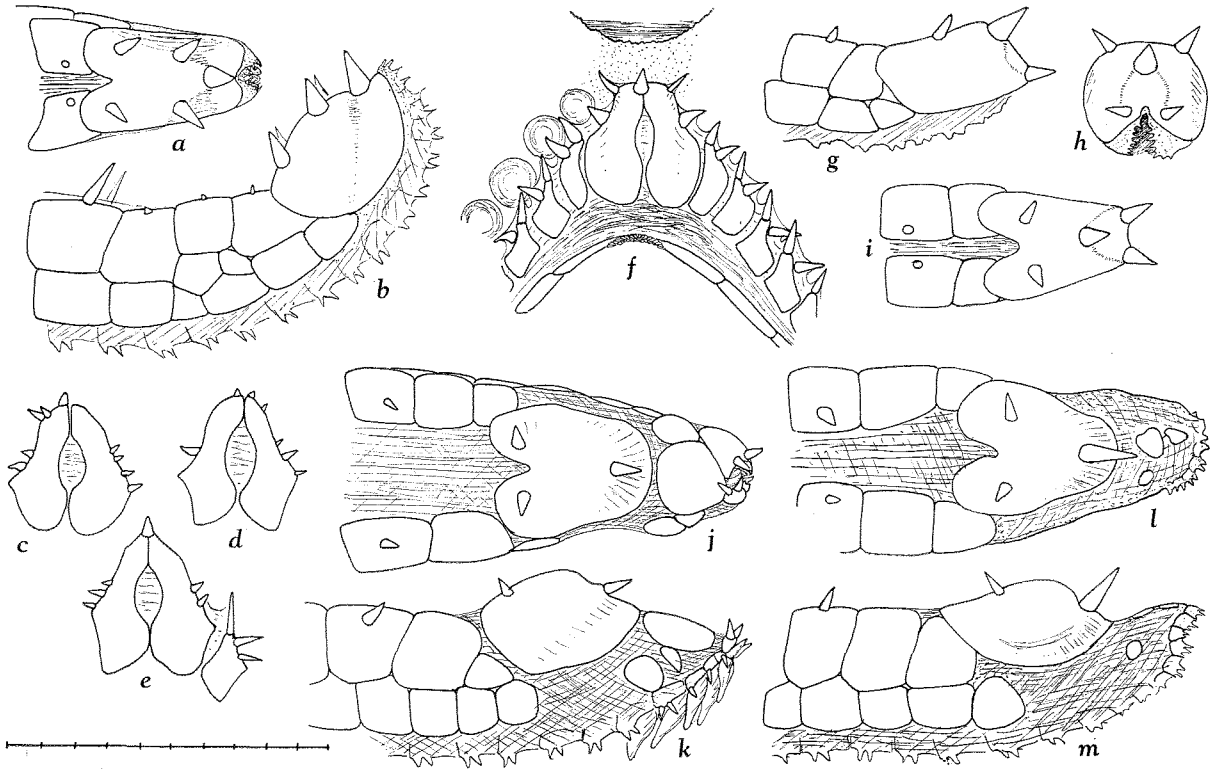

Fig. 22. *Porcellanaster cæruleus*. St. 52. a-e) R/r 32/11 mm; a-b, distal end of arm in dorsal view and in lateral view; c-e, different jaws. f-i) R/r 30/9 mm; g-i, a terminal ossicle in different views. j-m) R/r 36/11 mm; j-k and l-m, distal end of two arms in dorsal view and in lateral view respectively.
Scale: 10 mm.

slightly smaller subterminal ones, and a pair of small proximal dorsal ones (fig. 22*g-i*). In the medium-sized specimen there are also 5 spines, viz. the distal terminal one, and two pairs of slightly smaller proximal dorsal ones, whereas the usual subterminal pair is absent (fig. 22*a-b*). In the largest specimen there are 3 spines, the distal terminal one and a pair of proximal dorsal ones, the subterminal pair also here being absent (fig. 22*j-m*).

The dorsal side of the disk is provided with a fairly thick integument which – centrally and interradially, inside a line connecting the outer corners of the first superomarginal plates – is armed with uniformly scattered spinelets, each on its own small plate. All three specimens show a more or less distinct apical cone armed with minute spiniferous plates. The dorsal spinelets are rather spaced and not quite as numerous in the present specimens as they were in the slightly smaller type-specimen of LIEBERKIND's *irregularis*, but dorsal spinelets were sparser too in LIEBERKIND's two other almost as large specimens. The dorsal spinelets are mainly aciculate, but several, especially among those near the margin and near the arm bases, are terete, and some are slightly club-shaped, especially among those near the cribriform organs. In the smallest specimen the gonad papillae are observable near the corners of the cribriform organs. The madreporic body is circular, with a diameter about equal to the length of the first inferomarginal plate, and with the striae stretching across in radial direction or radiating from an adcentral point.

The adambulacral armature consists typically of 2 spiniform furrow spines, but in one specimen the first adambulacral ossicle, and also other scattered ones (no. 7 e. g.), may bear 3 furrow spines. The specimen with R/r 30/9 mm has 25-27 adambulacral ossicles.

The oral armature consists, besides of the conical proximal mouth-spine common to both the oralia forming a jaw, of 1-4 marginal spines laterally on each ossicle. In the smaller specimen there is thus 2 lateral conical spines subequal to the mouth-spine, one of them placed at the lateral proximal corner of the oral ossicle, the other near the corner adjacent to the adambulacralia (fig. 22*f*). In the largest specimen there is also generally 2 lateral spines on the oralia, though on one ossicle 3 such spines, viz. 2

small close-set ones distally, besides the one on the proximal lateral corner. In the medium-sized specimen the oral armature is fairly varying on different ossicles. Thus the usual unpaired mouth-spine may be replaced by 2 smaller spines, one to each oral ossicle in the jaw; and there may be only a single lateral spine on the distal part of the ossicle, or 2-4 lateral spines, also all on the distal part of the ossicle, or there may be 3 (2) distal lateral spines and 1 (2) proximal ones on the projecting lateral corner (fig. 22*c-e*).

A few remarks may be given here about the oral armature in the specimens of *P. irregularis* from the Valdivia st. 63. In the type-specimen the lateral oral spines on some ossicles are very slender, as figured by LIEBERKIND, but on other oralia – as a re-examination has shown – they are shorter and flattened, and so they are also in the two other specimens. The proximal lateral spine may almost assume the appearance of a segmental papilla, and on the ossicle there may be a faint indication of a segmental pit. In the type-specimen of *P. irregularis* one jaw is abnormal in having two unpaired mouth-spines, one above the other, as shown in LIEBERKIND's texfig. 3.

The ventrolateral area is paved with naked plates, partly in a smaller number than in the type of *P. irregularis,* but similarly arranged (cf. LIEBERKIND fig. 1, pl. 3) in indistinct radial rows, two of which about corresponding in width with that of a marginal plate, and with the most distal plates much smaller and more numerous so that about 4 of them adjoin each marginal plate.

In the smallest one of these three large specimens of *Porcellanaster* the arm ends are normal, with the adambulacral furrow ending below the terminal ossicle. In the medium-sized specimen the ambulacral furrow, however, extends up along the distal end of the terminal ossicle (fig. 22*a, b*), and in the largest specimen the ambulacral furrow extends on an elongation distinctly below and beyond the terminal ossicle. In four of the arms in this latter specimen the tip is unprotected, apart from some rudimentary plates (fig. 22*l, m*), whereas in the fifth arm a denser pavement of plates has been formed around the tip (fig. 22*j, k*).

It appears as if the specimens of *Porcellanaster* with a size of R/r about 30-32/9-11 mm and 8-9 superomarginal plates, have reached the full size obtainable by normal growth. (Of the other large specimens of *Porcellanaster* recorded in the literature, LIEBERKIND's *irregularis* with R about 30-33 mm has 8-7 superomarginals, and PERRIER's *granulosus* with R 24 mm has 8-9 superomarginals). Any further growth after such a size is reached becomes then apparently abnormal, as described for the present large specimen.

The specimens from Galathea st. 281, south of Ceylon (fig. 23*d-i*).

These three specimens, which correspond to SLADEN's *Porcellanaster caulifer,* have R/r 21/9 mm, 23/11 mm, and 24/11 mm. The first has an empty stomach, whereas the third has the stomach filled to the utmost, so that the diameter of the disk inclusive of the extremely widened mouth-opening becomes about 28 mm. The superomarginals (fig. 23*h*), 5-6 in number, are mainly subquadrate but sometimes slightly rectangular (in SLADEN's *caulifer* they were distinctly rectangular), and are armed with a fairly large erect dorsal spine; the distal plate possibly is unarmed, and scattered plates may be provided with an additional smaller spine, or with 2 subequal slender spines. The inferomarginals number 6-8, i. e. 1 or sometimes 2 more than the superomarginals. They are about two-thirds as high as the accompanying superomarginals. The cribriform organ may comprise from about 20 up to 34 lamellae. The terminal ossicle is rather globular (in this respect similar to SLADEN's *tuberosus*), in the smallest specimen armed with 3 spines, a distal terminal one and a pair of subterminal ones, and in the other specimens with 5 spines, there being also a proximal dorsal pair of small ones (fig. 23*h*). One ossicle in the large specimen has an extra subterminal spine to one side, and thus 6 spines in all (fig. 23*e*). In the same arm there is further an additional terminal ossicle riding on the antepenultimate superomarginal plate.

The dorsal side centrally and interradially bears spinelets, of which some – especially among those near the margin – are slightly clavate. The scattered perforated plates in the integument radially and in the arms, are slightly larger than the spinelet-bearing ones. All three specimens show a distinct apical appendage. Papulae occur in a broad band interradially. The gonad papillae are observable in some interradii in the smallest specimen.

The subcircular madreporic body is small, its diameter less than the width of the cribriform organ, or about equal to 1/2 or 1/3 of the width of the first inferomarginal plate, and the striae are irregularly arranged. The madreporic body is thus of a peculiar juvenile appearance considering the size of the specimens.

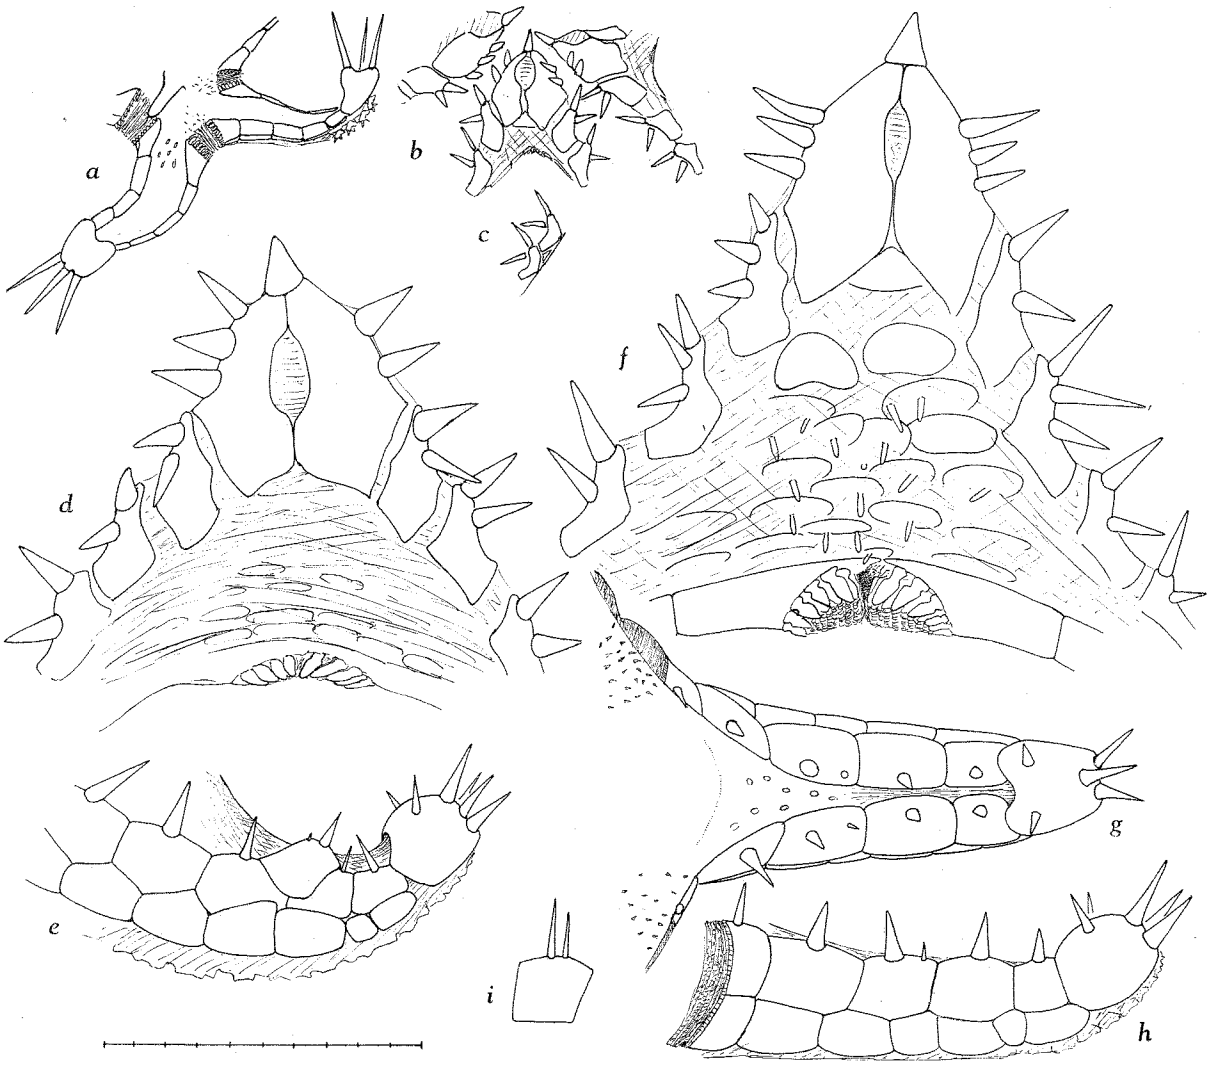

Fig. 23. *Porcellanaster cæruleus*. a-c) St. 282, R/r 7/2 mm; b, part of ventral side; c, adambulacralia nos. 6-7. d) St. 281, R/r 21/9 mm, part of ventral side in twice the usual scale. e) St. 281, R/r 24/11 mm, arm with supplementary terminal ossicle. f-i) St. 281, R/r 23/11 mm; f, part of ventral side in twice the usual scale; g-h, arm in dorsal view and in lateral view; i, superomarginal plate no. 4 in another arm.
Scale: 10 mm (in d and f: 5 mm).

The adambulacral ossicles generally carry 2 spines, but a few of the more proximal ones may bear 3 spines.

The oral armature consists of a stout proximal mouth-spine (one jaw in the larger specimen has 2 proximal mouth-spines, one to each ossicle), and 2-3 lateral spines, slightly longer than the proximal one, and sometimes about as stout, though generally distinctly more slender. The largest specimen has only 2 lateral oral spines, the mediumsized one mainly 3 (fig. 23*f*), and the smallest one 2 and 3 spines about equally common (fig. 23*d*).

The ventrolateral area is provided with a pavement of plates which are all naked in the smaller specimen, whereas a few of those in the larger specimen, and still a few more in the medium-sized one (fig. 23*f*) bear one or two small spines each. About 4 ventrolateral plates adjoin each of the marginal ones. The ends of the ambulacralia may be visible from about the third adambulacral ossicles.

The specimen from Galathea st. 282, south of Ceylon (fig. 23*a-c*).

This juvenile specimen of *Porcellanaster* has R/r 7/2 mm. There are 4-5 superomarginals, rectangular and unarmed, and a corresponding number of inferomarginals. Cribriform organs with about 8 lamellae. Terminal ossicle conspicuous and with 3 long slender glassy spines, a distal terminal one and a pair of subterminal ones. The disk bears in the

interradii close to the cribriform organs a number of spinelets, each on its own small plate, and in the integument radially there are scattered small rounded naked plates. There is a long apical appendage. The adambulacralia (12 in number) bear 2 spines. The oralia bear, besides the mouth-spine, 2-3 flattened spines laterally. Ventrolateral plates are not yet developed. The dorsal aspect of the specimen agrees with KOEHLER's fig. 5, pl. 11, 1909*a*; a few spinelets occurring interradially.

The specimen from Galathea st. 63, in the Gulf of Guinea (fig. 24*a-b*).

This juvenile specimen of *Porcellanaster* has R/r about 11/4-5 mm, 5 superomarginals, about twice as long as high, and 5 inferomarginals. The cribriform organ comprises about 18 lamellae. The conspicuous terminal ossicle bears 3, up to 2 mm long glassy spines. The disk is provided with a number of spinelets centrally and interradially, each on its own small plate; radially on the disk and in the arms the integument includes scattered small naked plates. The apical appendage is extended to a length of about 6 mm; its width is about 1/3 mm. The gonad papillae can be distinguished near the sutures between the first and second superomarginals. The madreporite is – as usual in the juvenile specimens – still of a small size in relation to the length of the adjoining marginals. The adambulacralia (15 in all) bear 2 rather long and slender spines, the proximal ossicles sometimes 3 spines. The oral ossicles bear 4 (in one case 3) lateral spines, somewhat shorter and more slender than the fairly stout mouth-spine. The ventrolateral area is provided with a few spaced small (rudimentary) plates with single spinelets. The stone canal is distinctly visible through the integument. In the oral opening are seen the test-fragments of a sea-urchin which, although small, has been large in proportion to the sea-star.

This small specimen corresponds fairly closely to the *Caulaster sladeni* described by PERRIER. It is slightly larger and has correspondingly one superomarginal plate more. (PERRIER also noticed the gonad papillae, though he did not recognize them as such). In the series of North Atlantic specimens from the Ingolf st. 36 listed in the table p. 128, the specimen corresponds to nos. X-XI.

The specimens from Pickle st. 92, near Cape (fig. 24*c-h*).

These two specimens are small, R 8 and 7 mm, and show in ventral aspect a rather different general appearance. The occurrence of two such specimens in the same catch supports the view that all hitherto recorded juvenile specimens of *Porcellanaster* belong to the species *cæruleus*.

The larger specimen with R/r 8/5 mm (fig. 24*c*) has 5 rectangular superomarginals and 5-6 inferomarginals. The cribriform organs are with about 10 lamellae. The terminal ossicles have 3 subequal spines, in one case 4, there being 2 spines side by side instead of the usual unpaired terminal one. Small embryonic plates are discernible dorsally around the long apical appendage, and further there are interradial bands of spinelets, each on its own small plate. Also a few pedicellariae occur interradially on the disk, often 1-2 close to the cribriform organ. The madreporite is of a diameter less than the width of the adjoining cribriform organ, the gonad papillae are well distinct. The adambulacralia, in a number of 10, bear each a pair of spines which form a large pedicellaria (fig. 24*e*), except the two or three distal rudimentary ones, which have only a pair of diverging flattened spines yet. The proximal adambulacral ossicle sometimes has an additional small aciculate spine on the adoral furrow corner, or, which is exceptional in *Porcellanaster* (and may be considered an abnormality), on the ventral surface of the ossicle at the interradial corner (fig. 24*d*). The oral ossicles have, besides a short conical mouth-spine, 3 lateral spines each, a proximal rather spiniform one and 2 flattened ones which as segmental papillae cover a distinct pit on the ossicle. In one case they seem to form a pedicellaria (fig. 24*e*) which when laid down fills out the pit on the ossicle. The ventrolateral area is armed with spaced small plates with spines.

This specimen agrees closely with the description of KOEHLER's *Albatrossaster richardi,* except that it has ventrolateral spinelets, whereas in *richardi* there were only spaced naked plates ventrally.

The other, slightly smaller specimen, with R/r 7/3-4 mm, has also 5 rectangular superomarginals, but still only 4-5 inferomarginals, the series of which do not quite reach to the terminal ossicle. This ossicle bears 3 spines, in one case 4, the distal terminal spine here being reduplicated (fig. 24*h*). The dorsal side is provided with some embryonic plates around the apical appendage and with interradial bands of spinelets, but is without pedicellariae. The gonad papillae are perceptible. The adambulacralia, 9 in number, bear generally 3 long slender and slightly flattened spines along their furrow mar-

Fig. 24. *Porcellanaster cæruleus*. a-b) Galathea st. 63, R/r 11/4 mm. c-e) Pickle st. 92, R/r 8/5 mm; d-e, two jaws in twice the usual scale. f-h) Pickle st. 92, R/r 7/4 mm; f, part of ventral side in twice the usual scale; g-h, terminal ossicles in twice the usual scale. i-k) Galathea st. 574; i, part of ventral side in twice the usual scale. l) Galathea st. 664, R/r 7/3 mm. m-o) Galathea st. 664, R/r 8/3 mm; m-n, dorsal pedicellariae in four times the usual scale; o, part of dorsal side in twice the usual scale. p-s) Galathea st. 664, R/r 4/2 mm; p, part of ventral side in four times the usual scale; q, part of dorsal side in twice the usual scale; r-s, arm in ventral view and in lateral view respectively, in twice the usual scale.
Scale: 10 mm (in a, d-i, o, and q: 5 mm, in m-n, and p: 2.5 mm).

gin (fig. 24*f*). Two of the proximal ossicles bear 4 furrow spines, and some more distal ossicles may have only two furrow spines. Not a single one of the adambulacralia has its armature formed as a pedicellaria. The oralia carry, besides the conical mouth-spine, 2, or sometimes 3, large flattened lateral spines, which have the appearance of segmental papillae over a segmental pit, or may simulate a pedicellaria. Ventrolateral plates are not yet developed.

The specimen from Galathea st. 574, southwest of Australia (fig. 24*i-k*).

This juvenile *Porcellanaster* has R/r 7/3.5 mm. There are 3 subquadrate superomarginals, slightly longer than high, and 3 inferomarginals about one-third as high as the superomarginals. The cribriform organs, except for that in the interradius with the madreporite, are still rather rudimentary, with only up to 6 lamellae. The conspicuous terminal ossicles carry 3 long spines. The whole dorsal side, also of the arms, still possesses the embryonic plating of rounded perforated plates, those around the apical appendage the largest, five interradial ones here being especially large. Some few spinelets occur near the cribriform organs, each on its own small plate. (A few plates are also found with 2 closely placed spinelets, rudimentary pedicellariae probably). The adambulacralia, 11 in number, each bears a pair of subequal lanceolate flat spines, apparently forming a transitional stage to a veritable pedicellaria. The oralia, besides the short conical mouth-spine, bear 3 subequal, flat pointed lateral spines. Ventrolateral plates are not yet developed.

This specimen agrees perfectly with SLADEN's *P. eremicus* from the South Atlantic west of Cape. Like this it has retained the embryonic plating of the dorsal side at a slightly larger size than hitherto recorded for juvenile North Atlantic specimens of *P. cæruleus,* but otherwise it is indistinguishable from these.

The specimens from Galathea st. 664, in the Kermadec Trench (fig. 24*l-s*).

The three juvenile specimens dredged here range in size from R 4 mm to R 8 mm.

The smallest one, R/r about 4/2 mm, has 3 subquadrate superomarginals and also 3 inferomarginals. Cribriform organs with up to 8 lamellae. Prominent terminal ossicle with 3 long spines. Dorsal side with the embryonic pavement of perforated plates (fig. 24*q*); close to the cribriform organs a few spinelets; also a few dorsal pedicellariae, one of which being merely two close-set spines. Adambulacralia, altogether 10, with 2 subequal, large lanceolate flat spines. Oralia with a fairly long conical mouth-spine and 3 flattened lateral spines (fig. 24*p*). No ventrolateral skeleton.

The medium-sized specimen, R/r 7/3 mm, has 4 superomarginalia, 3 inferomarginalia, and 11 adambulacralia. Cribriform organ with 8 lamellae. Dorsal side with the embryonic plating; no dorsal pedicellariae. The gonad papillae distinct near the sutures between first and second superomarginals. Oral and adambulacral armature as in the smaller specimen, only that the mouth-spine is shorter (fig. 24*l*).

The largest specimen, R/r 8/3 mm (fig. 24*o*), has 3 superomarginalia, 3 inferomarginalia and 11 adambulacralia. Oral and adambulacral armature as in the former specimen. Dorsally in the disk area the embryonic plating is in the state of being absorbed, a few of the perforated embryonic plates are still discernible, but otherwise only some circular markings in the integument indicate their former position and size. In the arms a close covering of plates is still present. Spinelets occur near the cribriform organs, and altogether 10-12 pedicellariae are scattered over the disk. The gonad papillae are discernible. A number of spaced small (rudimentary) plates occur in the ventrolateral areas.

These specimens agree well with SLADEN's *P. eremicus* and also with PERRIER's *Caulaster pedunculatus.*

Distribution:

Porcellanaster sensu stricte, probably a monotypic group: *P. cæruleus,* up to this date has been found in 86 dredgings scattered over all three oceans (fig. 38): 69 dredgings in the Atlantic from south of the Wyville Thomson Ridge to off Cape, eight in the northern Indian Ocean, three in the region of the Malay Archipelago, one in the northern West Pacific, two in the South Pacific, and three in the eastern tropical Pacific. The known bathymetrical range is from 1158 to 6035 m. (Most finds are made between 1600 and 3000 m, 7 (?) between 3000 and 4000 m, 4 between 4000 and 5000 m, 1 between 5000 and 6000 m, and a single one just below 6000 m). The bottom has been blue, green, white, grey, and black mud, globigerina ooze, transition clay, and red clay. The temperatures recorded range from 1.1° to 4.2°C.

Eremicaster Fisher, 1905

Type-species: *Eremicaster tenebrarius* Fisher, 1905 (= *Porcellanaster gracilis* Sladen, 1883).

Diagnosis:

Porcellanasterids with opposite superomarginals separate in whole arm length, and usually armed with dorsal spines. Terminal ossicle distal to arm end, not markedly broader than long. A mid-interradial suture. Three (-5) lamelliform cribriform organs. A single proximal mouth-spine, common to both oralia forming a jaw. Up to six radiating series of ventrolateral plates corresponding with a marginal plate. Lateral oral spines and aboral adambulacral spines sometimes modified as segmental papillae, covering as lids excavated pits on the ventral surface of the ossicles.

Description:

The general appearance of *Eremicaster* and its dorsal armature is like that of *Porcellanaster* (see p. 124). The genus is known to reach a size of R/r about 60/16-20 mm.

The number of cribriform organs may be fairly variable in some porcellanasterids, individually as well as with age, and is, therefore, not immediately acceptable as a generically distinguishing character. But, as discussed p. 125, also some other characters distinguish *Eremicaster* from *Porcellanaster*. Juvenile specimens of *Eremicaster* with yet only a single cribriform organ in each interradius usually may also be recognized by having the ventrolateral skeleton developed at a smaller size than is the case in *Porcellanaster*. Nevertheless, it is possible that some juvenile specimens of these genera may prove indeterminable.

Juvenile specimens of *Eremicaster* up to a size of about R/r 7/3 mm, in general have yet only a single cribriform organ developed in each arm angle, while all specimens on record with R about 8 mm or more, have 3 cribriform organs, at least in the interradius with the madreporite (specimens as large as with R 8-10 mm sometimes having yet only a single cribriform organ developed in the other interradii). Some large specimens of *Eremicaster* collected by the Galathea Expedition have 4-5 cribriform organs in one or more of the interradii.

The jaws bear as a general rule a single spine (the mouth-spine) on their proximal corner, at the junction of the two oral ossicles. But some jaws may be provided (atavistically?) with two proximal spines, one to each oral ossicle, and others even with a group of proximal spines. The number of lateral oral spines is also only small, and normally there are no suboral spines. The adambulacralia likewise bear only a few furrow spines and are normally devoid of any subambulacral armature. (Very exceptionally an oral or an adambulacral ossicle may be found provided with a spine or spinelet on the ventral surface). The lateral oral spines and the adorally placed adambulacral spines on the more proximal ossicles may be transformed into segmental papillae (see p. 42). The superomarginal plates bear usually a single, though sometimes more (up to 4), erect spine(s) on their upper edge. Some specimens, however, are devoid of spines on the superomarginals of the interradial angle, and spines may be totally absent along the whole arm. (The superomarginal spines are not markedly developed in juvenile specimens, and in specimens of the same population they may be present as well as absent). The ventrolateral plates are generally naked, but they may bear spines (e. g. all specimens known of LUDWIG's *E. pacificus*). And also some specimens belonging to species of *Eremicaster* with typically naked ventral plates, have been found provided with a scattered ventral spine-armature. The terminal ossicles in specimens of the same population may bear the usual 3 spines only, or also a great number of spines; and thus the conspicuous appearance of the terminalia in some specimens is of no definite taxonomic importance.

Remarks:

Two of the species described by SLADEN in 1883 in the genus *Porcellanaster, crassus* and *gracilis,* were distinguished by having three cribriform organs in each interradius, whereas the others, like the type-species *cæruleus,* had only a single cribriform organ in each arm angle. Further, these two species had part of their oral and adambulacral armature modified in a peculiar way, the spines being flattened, articulated on straight bases running parallel to the furrow, directed outwards from this, and each like a lid covering a pit on the surface of the oral or adambulacral ossicles. SLADEN named this a segmental organ (consisting of a segmental papilla at a segmental pit, see p. 42).

FISHER in 1905 described under the specific name of *tenebrarius* a form related to SLADEN's *crassus* and *gracilis,* likewise with 3 cribriform organs, and with segmental organs developed. He further considered these three forms representing a special subgenus of

Porcellanaster, which he named *Eremicaster,* with the species *tenebrarius* registered as the type.

LUDWIG, also in 1905, just a few days later than the appearance of FISHER's paper, published a paper including the description of two new species of *Porcellanaster, pacificus* and *waltharii,* which also had 3 cribriform organs, the first mentioned without segmental organs developed, and the last mentioned with such organs (the latter form proved to be exactly the same as FISHER's *tenebrarius*). In 1907 LUDWIG described another related form with 3 cribriform organs but no segmental organs: *vicinus,* and a variety of this form: *vicinus* var. *inermis.* In the same paper he raises *Eremicaster* to the rank of a genus, but uses as type incorrectly SLADEN's *crassus* (the first described species in the group) and considers the presence of segmental organs (papillae) the distinguishing character. *Eremicaster* in the sense of LUDWIG (1907) thus comprises the following forms, with segmental papillae and 3 cribriform organs: *crassus, gracilis, tenebrarius,* and *waltharii,* whereas the other forms, with 3 cribriform organs but without segmental papillae, viz. *pacificus* and *vicinus,* inclusive of var. *inermis,* were retained in *Porcellanaster.*

FISHER immediately (1907) protested against LUDWIG having changed the type of *Eremicaster,* from *tenebrarius* to *crassus;* and further he objected to using the segmental papillae as a taxonomic character, since he had found them in a very varying number in different specimens, the aboral furrow spine being transformed into a flattened lid-like papilla on from as few as 5 to about as many as 15 of the proximal adambulacral ossicles, and the number even varying considerably in specimens from the same catch. The distal part of an arm in a typical specimen of *Eremicaster* has thus always the same kind of adambulacral armature as has the whole arm of a specimen of *Porcellanaster* (with 1 cribriform organ only), and there is then but a slight step to the total disappearance of segmental papillae, for which reason FISHER concluded that it was the presence of 3 cribriform organs in each interradius which was the primary distinguishing taxonomical character. *Eremicaster* in his sense (he now also considers it of generic rank) consequently comprises the following forms: *crassus, gracilis, tenebrarius* (the type-species), *pacificus, waltharii, vicinus,* and *vicinus* var. *inermis.*

Of these *E. waltharii* (as noted by FISHER) is obviously the same as *E. tenebrarius,* which form, however, the present author considers the same species as *E. gracilis. E. pacificus* is a distinct species, and this also applies to *E. vicinus.* (The latter was by the present author formerly believed to be only a form of *E. pacificus* and therefore listed under this name in 1951 and 1956. Its specific validity has been confirmed, however, through the study of the present material).

The Galathea Expedition collected a total of 195 specimens of *Eremicaster* in six dredgings in the Indian Ocean and the tropical Pacific, two of the dredgings – in the Sunda Trench and the Kermadec Trench respectively – undertaken in hadal depths (more than 6000 m). The specimens from the two hadal dredgings belong to *E. vicinus,* and were described preliminarily in 1956, at which time *E. vicinus,* however, as mentioned above, was considered a form of *E. pacificus.* The other specimens of *Eremicaster* collected by the Galathea Expedition in the Indian Ocean, off tropical East Africa and south of Java, and in the eastern Pacific off Costa Rica, appear to represent two forms, which, however, may be only subspecifically different. One of the forms, identical with SLADEN's *P. crassus,* is represented by the specimens from the three abyssal dredgings in the Indian Ocean, the other form, identical with SLADEN's *P. gracilis,* but in the literature mainly re-

Key to the species of *Eremicaster*

		Page
1a.	Ventrolateral plates with spines. Terminal ossicle twice as broad as long. Papillae of covering fringe of cribriform organs very large, subquadrate ..... *pacificus*	160
1b.	Ventrolateral plates typically bare (only exceptionally scattered spinelets). Terminal ossicle about as broad as long. Papillae of covering fringe of cribriform organs not especially conspicuous ..	2
2a.	A distinct tubular apical appendage, surrounded by small spiniferous plates. So-called segmental organs frequently developed	3
2b.	No distinct tubular apical appendage, but possibly an apical cone. Central area of the disk with a pavement of fairly conspicuous plates. So-called segmental organs not developed ..... *vicinus*	161
3a.	Number of superomarginalia in proportion to that of adambulacralia about 1 : 2 ..... *crassus*	145
3b.	Number of superomarginalia in proportion to that of adambulacralia about 2 : 3 ..... *gracilis*	155

corded under the name of *E. tenebrarius,* is represented by the specimens from the dredging in the tropical eastern Pacific.

The two forms, *E. crassus* and *E. gracilis* (= *crassus* subspecies?), mainly differ from each other in the number of superomarginal plates in relation to the size of the specimens, their number being on the average somewhat lower in *crassus* than in *gracilis,* and their size thus correspondingly somewhat larger. The number of adambulacral ossicles in relation to the size of the specimens is the same in the two forms, and the difference between them therefore may best be expressed by the ratio of marginalia to adambulacralia. This ratio in the two forms overlaps however (cf. p. 52), and whereas it is easy to decide to which form a population represented by a fair series of specimens belongs, it may be impossible to do so if only single specimens are available, and these represent the extremes of variation in the particular form. The terminal ossicle is generally more conspicuous in *E. crassus* than in *E. gracilis,* but also this character is very variable. The two forms, *E. crassus* and *E. gracilis,* as far as our present knowledge goes however, certainly appear taxonomically different, but are perhaps best considered zoogeographical subspecies of the same species.

Eremicaster crassus (Sladen, 1883)
Fig. 25-28. Pls. XI-XII.

Porcellanaster crassus n. sp., SLADEN 1883 pp. 225-227; 1889 pp. 141-143, pls. 22_{4-7}, 27_{1-4}.
Eremicaster tenebrarius, MACAN 1938 pp. 327-329. (Non *E. tenebrarius* Fisher, = *gracilis* Sladen).

SLADEN described his *Porcellanaster crassus* from a single specimen taken by the Challenger in the mid-South Pacific (st. 286: 33°29′S, 133°22′W, 4271 m, red clay, 1.6° C.). It has R/r about 25/10.5 mm (SLADEN's texts of 1889 and 1883 says erroneously 35/10.5 mm); 7 (according to the figures -8) superomarginals, higher than long, and each with an upper erect spine; 9 rectangular inferomarginals; 3 lamelliform cribriform organs. Large, very prominent terminal ossicles, compressed laterally, high tubercular and rounded dorsally, and with 4 spines (SLADEN says that the fourth spine is in the dorsal median line, but really it is placed laterally to one of the sides). Disk area, except arm bases, with a uniform covering of single spinelets; a distinct apical appendage. Adambulacralia with 2 furrow spines, an adoral pointed one, and a median one, which is transformed into a segmental papilla for the greater length of the radius. (Number of adambulacralia 17, judging from the figures). Oralia with 2, as segmental papillae modified lateral marginal spines, besides the single conical mouth-spine. Naked ventrolateral plates.

The drawings of the type-specimen of *Porcellanaster crassus* in the Challenger report seem to agree perfectly with some specimens in the Galathea material, whereas the proportion R/r recorded by SLADEN, and his reference to a median dorsal spine, disagree with them. R/r when measured in the drawings, however, is about 25/10 mm, and thus the 35 mm in SLADEN's text of 1883 might be due to a printer's error, having passed unnoticed into the final edition of his report. Dr. AILSA M. CLARK of the British Museum kindly checked up on this, and confirms that there was an error in the measurement of R as given in the Challenger report. The type-specimen has all the arms curled vertically, and, according to dr. CLARK's re-examination, R is on the dorsal side about 20-21 mm and ventrally 30 mm, giving a mean value of about 25 mm. In the Galathea specimens of *Eremicaster* the armature of the terminal ossicles is very variable, never with a proximal median spine however, but often with one or more dorsal spines proximally to each side of the median line. When seen from the side the spines of such a possible proximal pair might overlap and in a figure appear as a single median spine. Dr. CLARK kindly re-examined also the terminal armature in the type of *crassus* and found, as expected, that the proximal spine was not quite median, being to the left in three cases and to the right in two cases, there being never more than a single proximal spine on any of the terminal ossicles. This arrangement falls well within the variation of the terminal armature in the Galathea specimens from e. g. st. 238, and the present author is thus convinced that these, as well as the specimens from sts. 217 and 474, represent the same species as SLADEN's *Porcellanaster crassus.*

FISHER (1907 and 1911) expressed the opinion that SLADEN's *Porcellanaster gracilis* was merely the juvenile *P. crassus,* but as will be discussed below, the case is not so simple as that. No doubt *P. gracilis* is very closely related to *P. crassus,* and possibly they are only to be considered subspecifically different, but according to our present knowledge they do represent two forms which show constant though rather slight differences. The form of which SLADEN's *P. gracilis* is the first described representative

also includes FISHER's new species *E. tenebrarius,* as shown below. Probably, however, not all specimens recorded under the name of *E. tenebrarius* really belong to this form; thus the specimens recorded from the Indian Ocean by MACAN in all probability belong to SLADEN's *P. crassus,* as will be discussed in the following.

MACAN in 1938 recorded and described under the name of *E. tenebrarius* 24 specimens of *Eremicaster* dredged by the Murray Expedition in the northwestern Indian Ocean off Somaliland (st. 171: 9°08'N, 55°30'E, 3840-3872 m), which specimens according to his tabular survey show a slightly lower number of superomarginals in relation to size than is found in the eastern Pacific specimens of *E. tenebrarius* described by FISHER, and, under the name of *P. walthariі,* by LUDWIG. This is the principal character by which the form *crassus* is distinguished from the form *gracilis,* as borne out by the study of the specimens available from the Galathea Expedition, and therefore the present author considers it justified to refer these Indian Ocean specimens to *E. crassus*. The Galathea Expedition also collected specimens of *E. crassus* in two neighbouring localities, but did not find *E. gracilis* (= *tenebrarius*) in the region.

MACAN's specimens have R/r in mm as follows, with the number of superomarginals added in parentheses: 6/3 (4), 6/3 (5), 7/3 (3), 7/3 (5), 7/3 (5), 7/3 (5), 7/3 (5), 7/3 (5), 8/4 (4), 9/4 (5), 10/4 (5), 10/4 (5), 10/5 (5), 11/5 (5), 15/6 (5), 15/7 (7), 16/7 (6), 16/7 (6), 20/8 (7), 22/8 (8), 23/10 (9), 28/11 (8), 30/10 (11), and 33/12 (12). MACAN states that "the specimens agree closely with the description of the American forms", and the correctness of this statement is not disputed, considering the insignificance of the differences by which the two forms are to be recognized. MACAN states that the typical number of cribriform organs does not appear till the specimens have reached R 8 mm, and that superomarginal spines in general do not appear till they have reached R 10 mm, and may be wanting on the interbrachial plates in specimens up to R 16 mm. The small specimens have 3 terminal spines, the larger ones 5.

The Galathea material:

A total of 100 specimens of *Eremicaster* referable to SLADEN's species *crassus* were collected in three dredgings in the Indian Ocean, viz. in the western part, in the Mozambique Channel and off Kenya respectively, and in the eastern part south of Java.

St. 217: 14°20'S, 45°09'E, 3390 m, 1.6°C., globigerina ooze. 64 specimens.

St. 238: 3°23'S, 44°04'E, 3960 m, 1.8°C., globigerina ooze. 22 specimens.

St. 474: 9°49'S, 114°13'E, 3840-3810 m, 1.2°C. 14 specimens.

The specimens available from st. 217 range in R/r from 7/3 to 25/10 mm, those from st. 238 from 29/9 to 44/13 mm, and those from st. 474 from 9/4 to 58/14 mm. The three populations represented are treated separately in the following, since the two former samples supplement each other with regard to size, and since the third, from st. 474, includes several specimens without the least indication of so-called segmental organs, i. e. with all the furrow spines, inclusive of the lateral oral spines, distinctly acicular.

The population from st. 217. (Fig. 25. Pl. XI 1-6):

The 64 specimens from st. 217 have R/r in mm as follows, with the number of superomarginals added in parentheses: 7/3 (4-5), 8/3 (5), 8.5/3.5 (6), 9/3 (5), 9/3.5 (5), 10/4 (5), 10/4.5 (5), 11/4 (6), 12/5 (6), 13/4.5 (6), 13.5/4.5 (6), 14/5 (6), 14/5 (7), 14/5 (7), 14/5 (7), 14/5 (7), 15/5 (6), 15/5 (7), 15/5 (7), 16/5 (7.5), 16/5 (7-8), 16/6 (9-10), 17/5 (8), 17/8 (9), 18/6 (7), 18/6 (7), 18/6 (7), 18/6 (8), 18/6 (8), 18/6 (8), 18/6 (8-9), 18/6 (9), 18/7 (8), 18/7 (8), 18/7 (8), 18/8 (9), 19/7 (7), 19/7 (8-9), 19/7 (9), 19/7 (9), 19.5/7 (8), 20/6 (8), 20/6.5 (8), 20/7 (7-8), 20/7 (8), 20/7 (9), 20/7 (9-10), 20/8 (7), 21/6 (9), 21/7 (8), 21/7 (9), 21/8 (8), 22/7 (8-9), 22/7 (9), 22/8 (9), 22/9 (8-9), 22/9 (9-10), 23/6 (10), 23/7 (9), 23/7 (9), 23/8 (8), 24/9 (9-10), 24/9 (9-10), and 25/10 (9-10) mm.

The ratio R/r ranges in these specimens from 2.3 (exceptionally 2.1) to 3.3 (exceptionally 3.5), being $\leqq 3$ in all specimens with R 7-16 mm, but occassionally also < 3 in specimens with r up to 2.5 mm, and > 3 only in specimens with R 20 mm or more.

The number of superomarginal plates in relation to the size of the specimens is as follows:

R in mm	Number of superomarginals
7	4-5
8-10	5
8.5-14	6
14-16	7
16-23	8
17-25	9
20-25	10

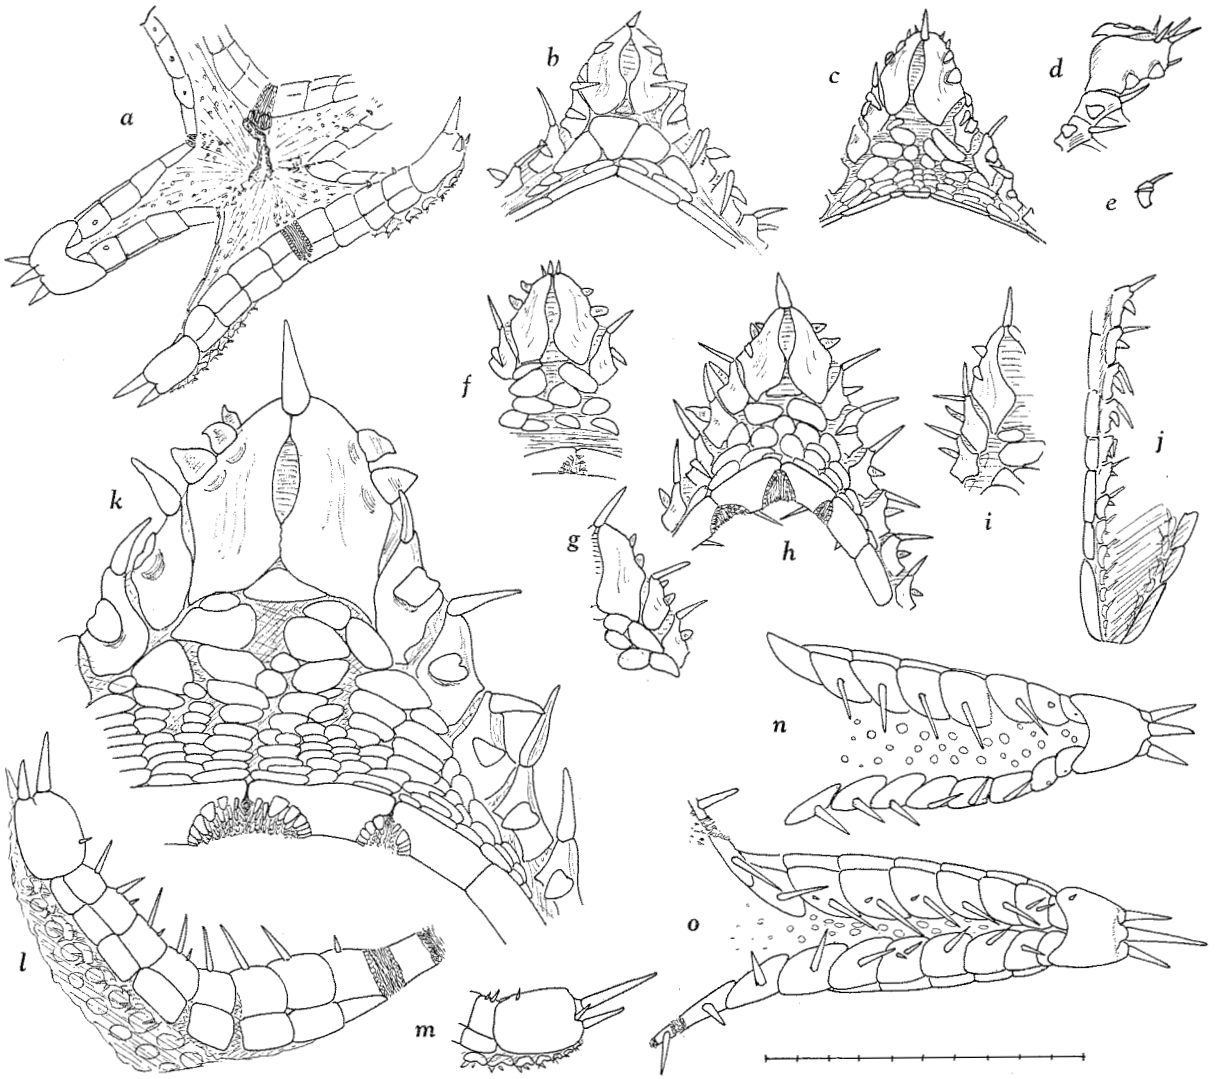

Fig. 25. *Eremicaster crassus*. St. 217. a-b) R/r 7/3 mm; b, part of ventral side in twice the usual scale. c) R/r 19/7 mm. d-e) R/r 20/7 mm, oral ossicle and proximal adambulacralia seen obliquely from the side, and adambulacral ossicle no. 12. f-j) R/r 22/9 mm; f-i, different jaws; j, distal end of arm in ventral view. k-o) R/r 24/9 mm; k, part of ventral side in twice the usual scale; l-o, different arms in different views.
Scale: 10 mm (in b and k: 5 mm).

The interbrachial superomarginal plates are rather subquadrate, and also the proximal superomarginals in the arms are usually subquadrate, though with the upper corners, especially the aboral one, rounded. The same description may apply also to the more distal superomarginals (fig. 25*l*), but often these are subrhomboid with the aboral margin slightly concave and the adoral margin convex (fig. 25*o*). The aboral margin of the superomarginals usually is slightly overlapped by the adoral margin of the following plate (fig. 25*n, o*). In the juvenile specimens with R up to 12 mm, the superomarginals are more rectangular and do not overlap each other distinctly. The inferomarginal plates correspond in number to the superomarginals (perhaps being one or two more distally) and lie nearly always exactly below their superomarginal companions. They are somewhat lower than these, about two-thirds their height, and are rather regularly rectangular.

All the specimens from st. 217 are provided with superomarginal spines, borne on the plates near their dorsal edge. In the juvenile specimen with R/r 7/3 mm (fig. 25*a*; pl. XI 1) the superomarginal spines are still mere granula and present only on the arm plates, whereas the interbrachial plates are still unarmed; and they are rudimentary too in the other small specimens with R up to 11 mm. In all larger specimens the superomarginal spines are well devel-

oped. In general there is only a single spine to each plate, erect, slender, spiniform, pointed, and up to about one-third longer than the height of the plate. The spines on the first superomarginals, between the cribriform organs, are often somewhat smaller than those on the second and third plates, and are totally absent in a specimen with R/r 22/9 mm. The following spines are subequal in size almost for the whole length of the arm. Some few (about 10 %) of the specimens are provided with two spines on some plates, exceptionally even three, but then smaller spines.

The number of cribriform organs is still only 1 in each interradius of the juvenile specimens with R/r 7/3 (fig. 25*a*) and 8/3 mm, and also in a few of those with R/r about 9/3 mm. In other specimens with R/r 9/3 to 10/4.5 mm there is in one or more of the interradii a rudimentary cribriform organ present to each side of the median one, consisting at first of only a single row of papillae to the proximal side of the marginal suture. Three cribriform organs become developed first in the interradius with the madreporite. All the specimens with R/r 11/4 mm or more, and 6 or more superomarginal plates, have 3 distinct cribriform organs of a lamelliform structure in each interradius.

The terminal ossicle (fig. 25*l-o*) is distal to the arm end, and slightly larger than this, rather cubic-shaped, with the proximal dorsal margin concave, and with 3-7 spines. Generally there are only the usual three spines on the obtuse distal end of the ossicle, a larger distal terminal one outwards directed above the furrow, and a pair of smaller subterminal ones, one to each side of the end of the furrow and likewise outwards directed. (Exceptionally there are 2 subterminal spines to one or to both sides of the furrow). Some terminal ossicles however, also bear spines or spinelets proximally on their dorsal side, usually a single pair, with one spine to each side (or only one of these spines developed), but occasionally two pairs, with 2 spines to each side of the dorsal mid-line (or 1 and 2). Different terminal ossicles in the same specimen may bear 3 or 5 (4) spines, or 5 and 7 (6) spines. Five terminal spines occur e. g. in a small specimen with R/r 13/4.5 mm, but otherwise the larger number of terminal spines is found mainly in large specimens.

The dorsal side is covered by a fairly thin integument. In the smallest specimen, R/r 7/3 mm, there are in the arms and radially on the disk spaced small rounded perforated plates (the embryonic plates), whereas interradially and mainly near the margin there is a small number of slightly smaller plates, each bearing a single spinelet. This small specimen (fig. 25*a*) has a relatively long apical appendage, with crowded minute plates with minute spinelets. The interradial spine-bearing plates gradually increase in number in the large specimens, and the apical appendage become relatively smaller, being of about the same size in all the specimens, inclusive of the largest ones. The small spine-bearing plates may be fairly crowded, and centrally, around the apical appendage, and near the margin interradially, they may form a close pavement. In the arms, and in the arm bases outside a tangential line connecting the distal corners of the outermost cribriform organs, however, there is always only spaced naked perforated plates of a size of up to 0.3-0.5 mm in diameter, and those of arms on an average slightly larger than those of disk area. Papulae were not perceptible in any of the specimens.

The madreporite is subcircular, with a diameter equal to the width of the first superomarginal plate. It lies close to the marginal plates, sometimes displacing them somewhat, and possibly being almost marginal in position. It is deeply furrowed, and generally with some furrows stretching across in the interradial line of the specimen, whereas the others radiate from the center.

The adambulacral ossicles number about twice as many as the superomarginal plates, as shown by the following examples:

R/r in mm	Number of superomarginalia	Number of adambulacralia
7/3	4-5	10-11
19/7	7-8	15
19/7	7	15
22/9	9-10	20
24/9	9-10	21

The last four, rudimentary adambulacralia are found below the terminal ossicle.

The adambulacral armature typically consists of 2 furrow spines. The adoral one is long (about the length of the ossicle), slender, triangular in section, pointed, and often slightly curved, and is borne on the adoral corner of the ossicle which is protruding somewhat into the furrow. The aboral spine, which is placed medially on the furrow margin, is on the proximal adambulacralia usually transformed into a segmental papilla (a flat subquadrate, subtriangular, or heart-shaped spine), whereas more distally it is rather spiniform, though flattened and always

shorter than the adoral spine. Some of the proximal adambulacralia may bear 3 furrow spines, usually 2 spiniform ones adorally, and a single one modified as a segmental papilla aborally, only exceptionally 1 adoral spiniform spine and 2 aboral segmental papillae.

The oral ossicles are typically at their tip provided with the single conical fairly large mouth-spine, common to both ossicles forming the jaw (fig. 25*k*). A single specimen has two mouth-spines to each jaw however, one above the other; and in one specimen a jaw is found with a group of 3 small spines at the tip (fig. 25*f*); and in still another specimen there is a jaw with 4 proximal small spines, 2 to each ossicle (fig. 25*d*). It is possible that such abnormalities have arisen by irregular regeneration of lost mouth-spines. Laterally each oral ossicle is usually provided with two marginal spines in the form of segmental papillae, being broad and flattened and covering a pit on the ossicle. In a few of the specimens it is only the distal marginal spine which has the appearance of a segmental papilla, whereas the proximal one is acicular, and only exceptionally both lateral spines are rather spiniform, not modified as distinct segmental papillae. Some few (about 10 %) of these specimens from st. 217 are provided with an additional third small spiniform oral spine on the proximal lateral corner of the ossicle (fig. 25*d*), deeper in the mouth than the other marginal spines. Some oralia have two such additional spines, thus 4 lateral spines in all. Sometimes only the proximal additional spine is spiniform, whereas the distal one is flattened, there being thus 3 lateral segmental papillae.

The ventrolateral area is provided with a pavement of naked plates. In the small specimen with R/r 7/3 mm, the ventrolateral plates are only few and relatively large, extending as far as to the second inferomarginals (fig. 25*b*), whereas in the largest specimens they are numerous and extend as far as to the fourth inferomarginals. The distal ventrolateral plates, near the marginals, are transversely elongate, small (rudimentary) and arranged in indistinct radiating series, four to six to a marginal plate (fig. 25*k*); the plates near the oralia are much larger and irregularly shaped. In the larger of these specimens from st. 217 there are about 10 indistinct tangential rows of ventrolateral plates, the most proximal row typically with only two plates, the second row with four somewhat smaller plates, and then outwards a gradually increasing number of still smaller plates.

The population from st. 238. (Figs. 26 and 27. Pl. XI 7-12):

The 22 specimens of *Eremicaster* available from this station have R/r in mm as follows, with the number of superomarginals added in parentheses. 30/10 (10), 32/11 (10), 34/12 (11), 34/13 (11), 35/11 (10), 35/11 (10), 36/12 (11-12), 37/11 (10-11), 37/11 (11-12), 37/13 (13), 37/13 (13), 38/10 (12-13), 38/11 (11-12), 39/11 (12-15), 39/13 (12-13), 40/11 (14-15), 40/13 (13-14), 41/13 (14), 42/12 (13-14 (-15-16)), 43/12 (13), 43/13 (14-15 (-16-17)), 43/14 (11-12).

These specimens are thus somewhat larger than those described from st. 217, and supplement these in the survey of the variation and change in the characters with growth. With increasing size also the range of variation in number of superomarginals increases. The specimen with R/r 39/11 mm has 12 superomarginals in a regular sequence in four arms, but 15 are present in one arm. The largest specimen, R/r 43/14 mm, has a regular sequence of only 11-12 superomarginal plates, whereas another of about the same size, R/r 43/13 mm, has 14-15 superomarginals in regular sequences, and, in addition, a few extra ones inserted distally in some of the arms, but not reaching to the inferomarginals (fig. 26*k*). The same also applies to a specimen with R/r 42/12 mm.

All the specimens from st. 238 have, in accordance with their fairly large size, well developed superomarginal spines, usually tapering spiniform (fig. 26*a*), but occasionally somewhat flattened and spearhead-shaped (fig. 26*h, i*). All the specimens have also at least some superomarginals provided with 2 or sometimes 3 spines, exceptionally even 4 spines. In some specimens nearly all superomarginals bear 2-3 spines, i. e., either two about subequal ones, or a medially placed one with a smaller somewhat diverging one to each side. The spines on the first superomarginals are often smaller than the others.

The cribriform organs number 3 in each interradius in all the specimens. Only one specimen, R/r 31/13 mm, shows a slight irregularity in one of the interradii, in which to one side there are three superomarginal plates corresponding with two inferomarginal ones. Cribriform organs are here developed around each of the two superomarginal vertical sutures, which correspond to a single inferomarginal one, and so there in this arm angle are 4 cribriform organs on the series of superomarginal plates.

The terminal ossicle may bear 3 spines only,

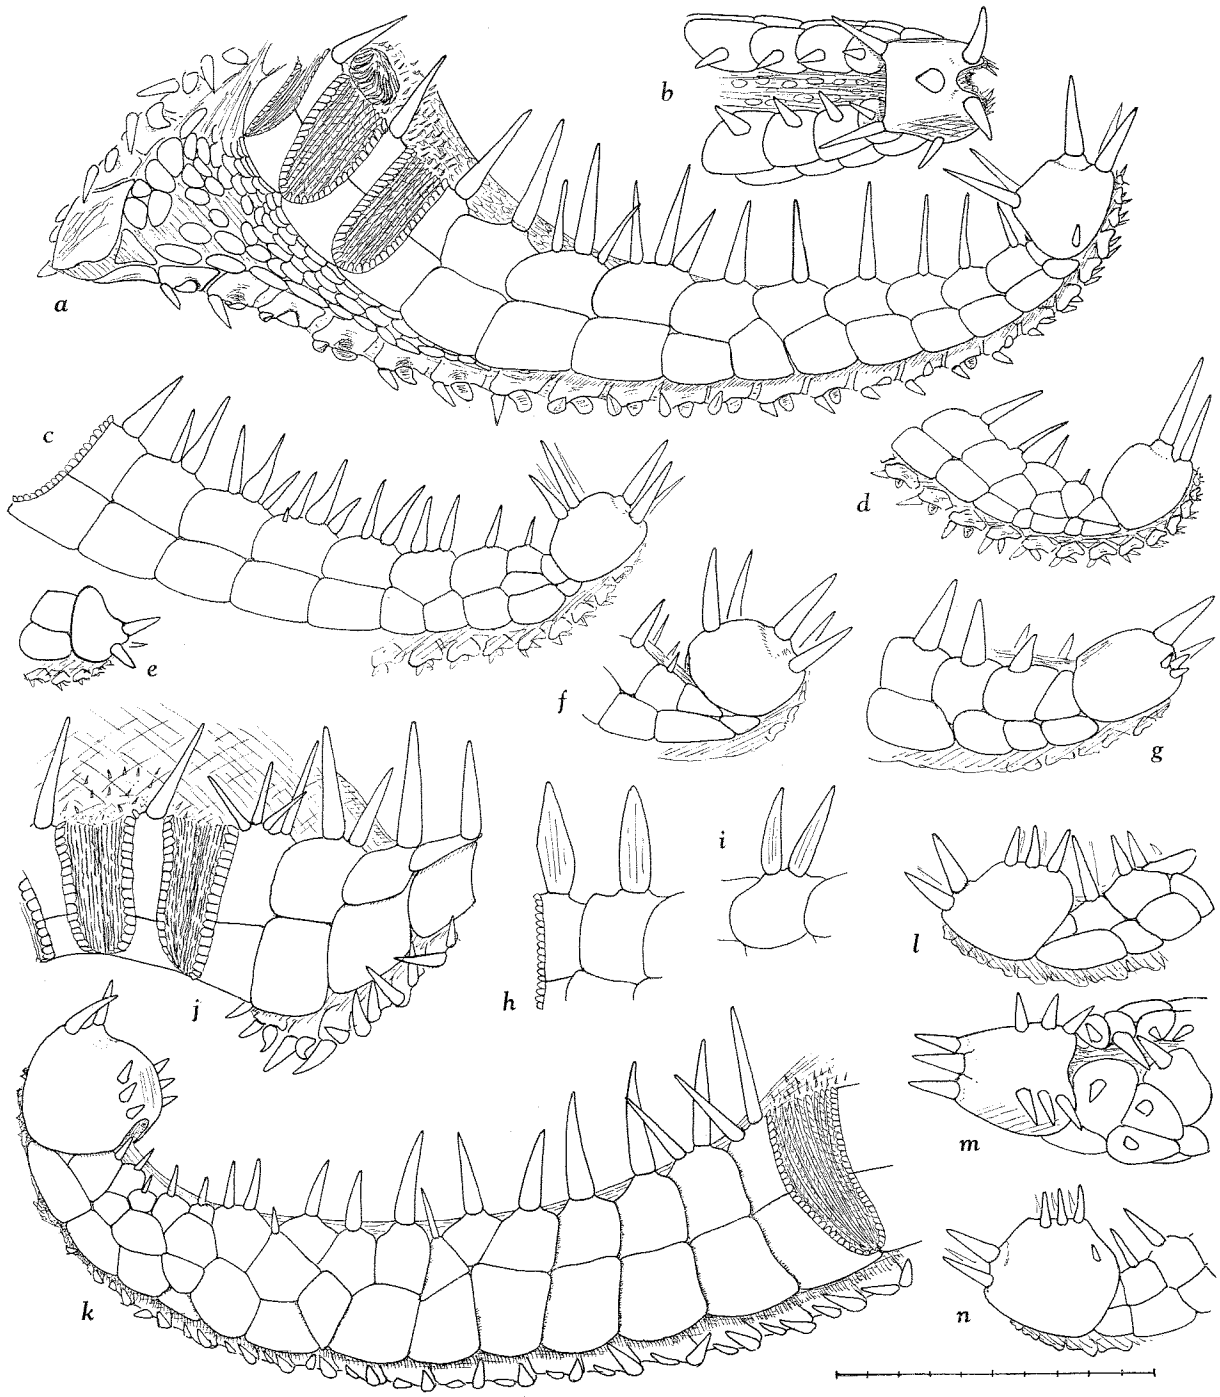

Fig. 26. *Eremicaster crassus*. St. 238. a-b) R/r 36/11 mm, same arm. c) R/r 30/10 mm (see also fig. 27 m.n). d) R/r 37/13 mm. e) R/r 42/12 mm, abnormal terminal ossicle, (see also fig. 27 o-p). f) R/r 37/11 mm (see also fig. 27 c-d). g) R/r 43/12 mm. h-i) R/r 41/13 mm, superomarginals nos. 2-3 and 6 respectively. j-n) R/r ab. 43/13 mm; j, arm angle; k, arm in lateral view; l-m, distal end of another arm in lateral view and in dorsal view; n, distal end of a third arm in lateral view. Scale: 10 mm.

thus e. g. in the specimen with R/r 37/13 mm (fig. 26*d*). Usually, however, the terminal ossicles are provided with an additional pair of spinelets on their proximal surface (as was also the case in some of the specimens from st. 217), and there may be up to three pairs of proximal dorsal spines, as e. g. in a specimen with R/r 43/13 mm (fig. 26*k, n*). The terminal ossicle may further bear a spine or spinelet on its lateral side near the lower margin, as e. g. in a specimen with R/r 36/11 mm (fig. 26*a*), or closer

to the upper lateral margin, as in the specimen with R/r 43/13 mm. Thus a single terminal ossicle may be provided with as many as 11 spines. Also the subterminal spines may, though rarely, be reduplicated. Often the terminal ossicles of the same specimen bear different numbers of spinelets, 3-4 or 5-more. In the preserved specimens the terminal spines are frequently lost or broken. Perhaps they are also easily damaged in life. A few terminal ossicles have only a small distal spinelet, and then it possibly is in regeneration. As mentioned above, it seems that when the tissue has been damaged, a group of minute spines may develop instead of the usual large single one.

The appearance of some of the terminal ossicles in these specimens from st. 238 is exactly the same as in the specimens from st. 217, but others are much more swollen and conspicuous in relation to the size of the arms. Such specimens agree closely with SLADEN's type-specimen of *P. crassus,* which has convinced the present author that all these specimens from st. 238 as well as those from st. 217, are representatives of this species. Generally the terminal ossicle is longer than high, but occasionally the reverse is the case, as in a specimen with R/r 37/11 mm (fig. 26*f*).

The dorsal armature shows no variation from that described for the larger of the specimens from st. 217. Papulae however, were to be seen in a few of the large specimens, scattered between the interradial spinelets, and of about the same size as the basal plates of these. An apical appendage is present in all the specimens. In one specimen, R/r 59/13 mm, the gonad papillae were discernible close to the distal corner of the first superomarginal plate.

The adambulacralia number about twice as many as the superomarginalia, and this is the case in all specimens, from the smallest to the largest ones present, e. g.

R/r in mm	Number of superomarginalia	Number of adambulacralia
30/10	10	21-22
30/11	11-12	25
37/13	13	26
37/13	9-11	20-21
42/12	13-14	29-30
43/13	16-17	30
43/14	11-12	23-25

The adambulacral armature may be exactly as described for the specimens from st. 217, consisting of two spines of which the adoral one on the protruding corner of the ossicle is fairly long spiniform (perhaps triangular in cross-section) pointed and often slightly curved, whereas the aboral one (on the more proximal adambulacralia) is modified as a distinct segmental papilla, hollowed out, and usually with a rounded end, as shown in fig. 27*j, p, s*. In one specimen, however, it is very broad, square-shaped and with a peculiarly dented outer margin (fig. 27*d*), and in others it has the end more or less drawn out, and is then rather hook-shaped (fig. 27*u*), and thus can hardly be designated as a segmental papilla. In the latter cases also the adoral spine may be broad flattened and more or less hook-shaped. Segmental pits are distinct on the adambulacralia of some specimens, but are in others hardly – if at all – discernible. In most of these specimens from st. 238, the aboral furrow spine though broad and flattened, is not at all formed as a segmental papilla. And it may be a slender though flattened spine. Three adambulacral spines occur exceptionally on scattered ossicles, and then it is always the adoral spine which is reduplicated (fig. 27*c*). In a single specimen, R/r 30/10 mm, some of the distal adambulacralia were found to be provided with a small spinelet on their surface.

The oral armature shows about the same variation as described for the specimens from st. 217. The usual single mouth-spine may be replaced by 2 spines, one to each oral ossicle, or by a group of small spinelets to each oral ossicle (fig. 27*s*). In the same specimens, however, there are also jaws with the usual single conical spine at the tip. The two lateral oral spines are subequal to the aboral furrow spines of the proximal adambulacralia, and thus in general modified as segmental papillae, flattened and somewhat hollowed, and with either a pointed or a rounded distal end. Occasionally the end of the oral papillae is drawn out into a curved slender tip, giving the papillae a shape like a hook, or the papillae are very broad (square-shaped) and have the distal end dentate. The segmental papillae generally fit into a segmental pit on the ossicle, but such a pit is not always discernible. Also a few specimens in this population have a third lateral oral spine, proximally to the usual two, somewhat deeper in the mouth, generally spiniform (fig. 27*h*), but sometimes modified as a third segmental papilla. Exceptionally all the lateral oral spines are spiniform, and this may be the case also in specimens with adambulacral segmental papillae. A single oral ossicle in a specimen with R/1 39/13 mm bears on its surface, midway between the lateral squamiform spines and the suture, a small spiniform spine, and

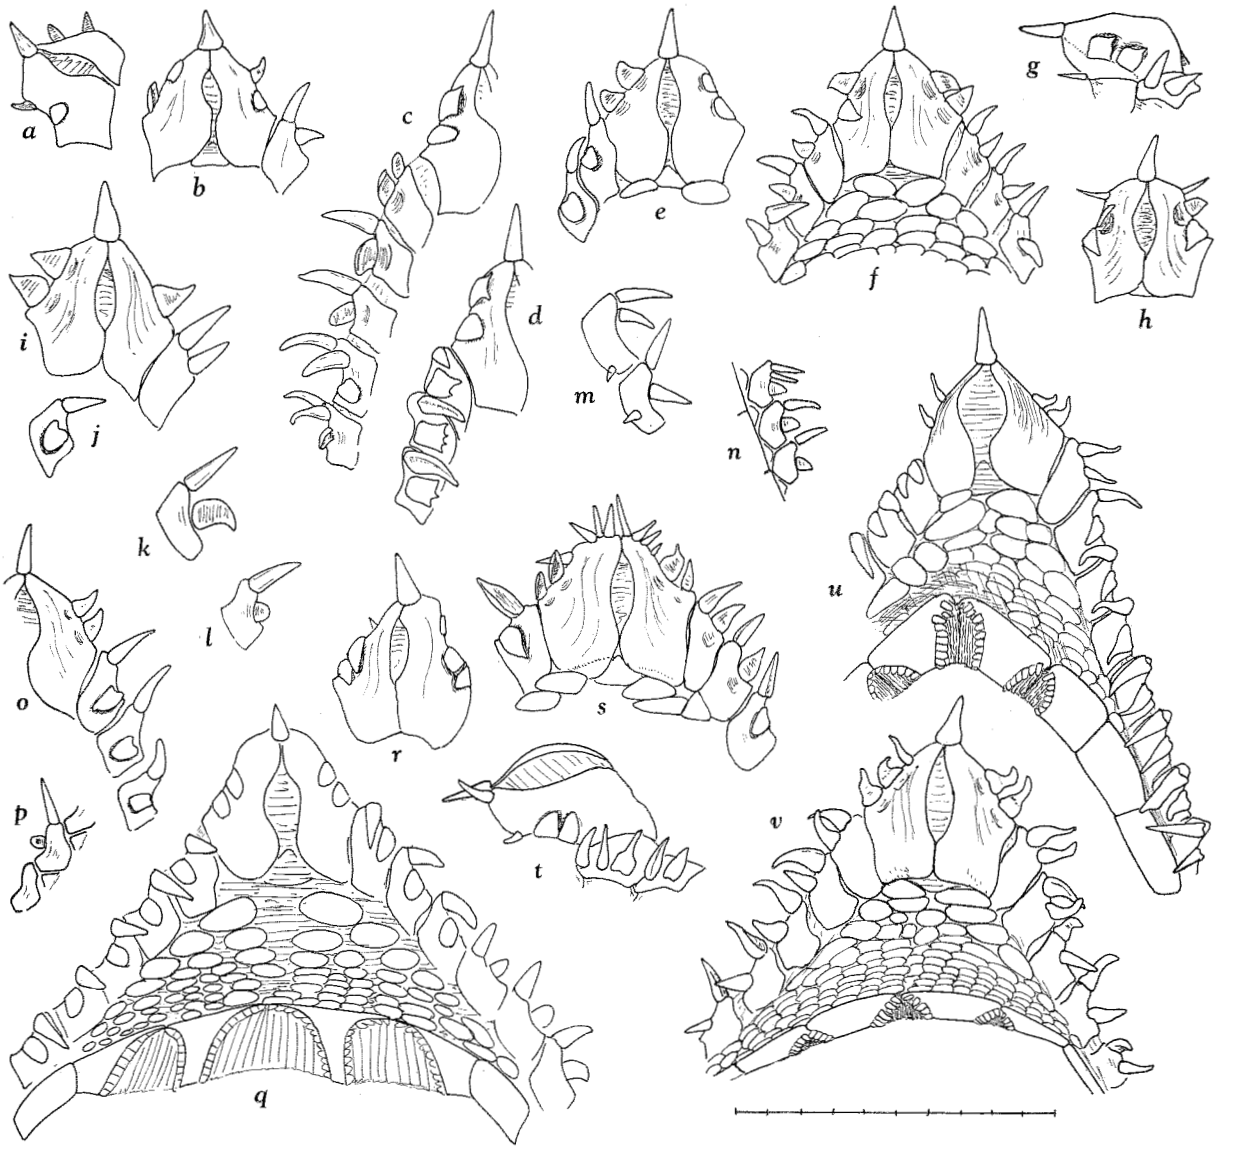

Fig. 27. *Eremicaster crassus*. St. 238. a-b) R/r 32/11 mm, two jaws in different views. c-d) R/r 37/11 mm (see also fig. 26 f). e) R/r 36/11 mm. f-h) R/r 37/13 mm; g-h, same jaw in lateral view and in ventral view. i-j) R/r 36/12 mm, j, adambulacral ossicle no. 4. k) R/r 43/13 mm, adambulacral ossicle no. 4. l) R/r 34/13 mm, adambulacral ossicle no. 5. m-n) R/r 30/10 mm; m, adambulacralia nos. 15-16, in twice the usual scale; n; adambulacralia nos. 12-14, (see also fig. 26 c). o-p) R/r 42/12 mm; p, adambulacral ossicle no. 14. q-t) R/r 41/13 mm, different jaws. u-v) R/r 40-44/12-13 mm, different jaws. Scale: 10 mm (in m: 5 mm).

this is the only case hitherto recorded of a suboral spine in the group of *Eremicaster*.

The ventrolateral area is as described for the specimens from st. 217.

The population from st. 474. (Fig. 28. Pl. XII).

The 14 specimens of *Eremicaster crassus* represented from this station range in size from a juvenile to one almost as large as any one on record. They have R/r in mm as follows, with the number of superomarginals added in parantheses: 9/4 (5), 14/5.5 (6), 18/6 (6), 22/6.5 (7), 29/7 (9), 31/11 (9), 31/11 (10), 34/9.5 (10), 35/11 (12 (-13)), 36/10 (10-11), 37/11 (10), 37/14 (12-14), 43/12.5 (13-14), 58/14 (15-16).

The ratio R/r ranges from 2.2 by R 9 mm to 4.1 by R 58 mm, but may be 4.1 also in a specimen with R only 9 mm, and 2.7 in a specimen as large as with R 37 mm. The superomarginal plates are regularly arranged in all the specimens. The inferomarginal ones generally lie exactly below their superomarginal companions for the greater length of the arms, but are distally often present in a number of 1-2 more. They number e. g. 8 in the specimen with R/r 18/6 mm and 6 superomarginals, and 15-16 in

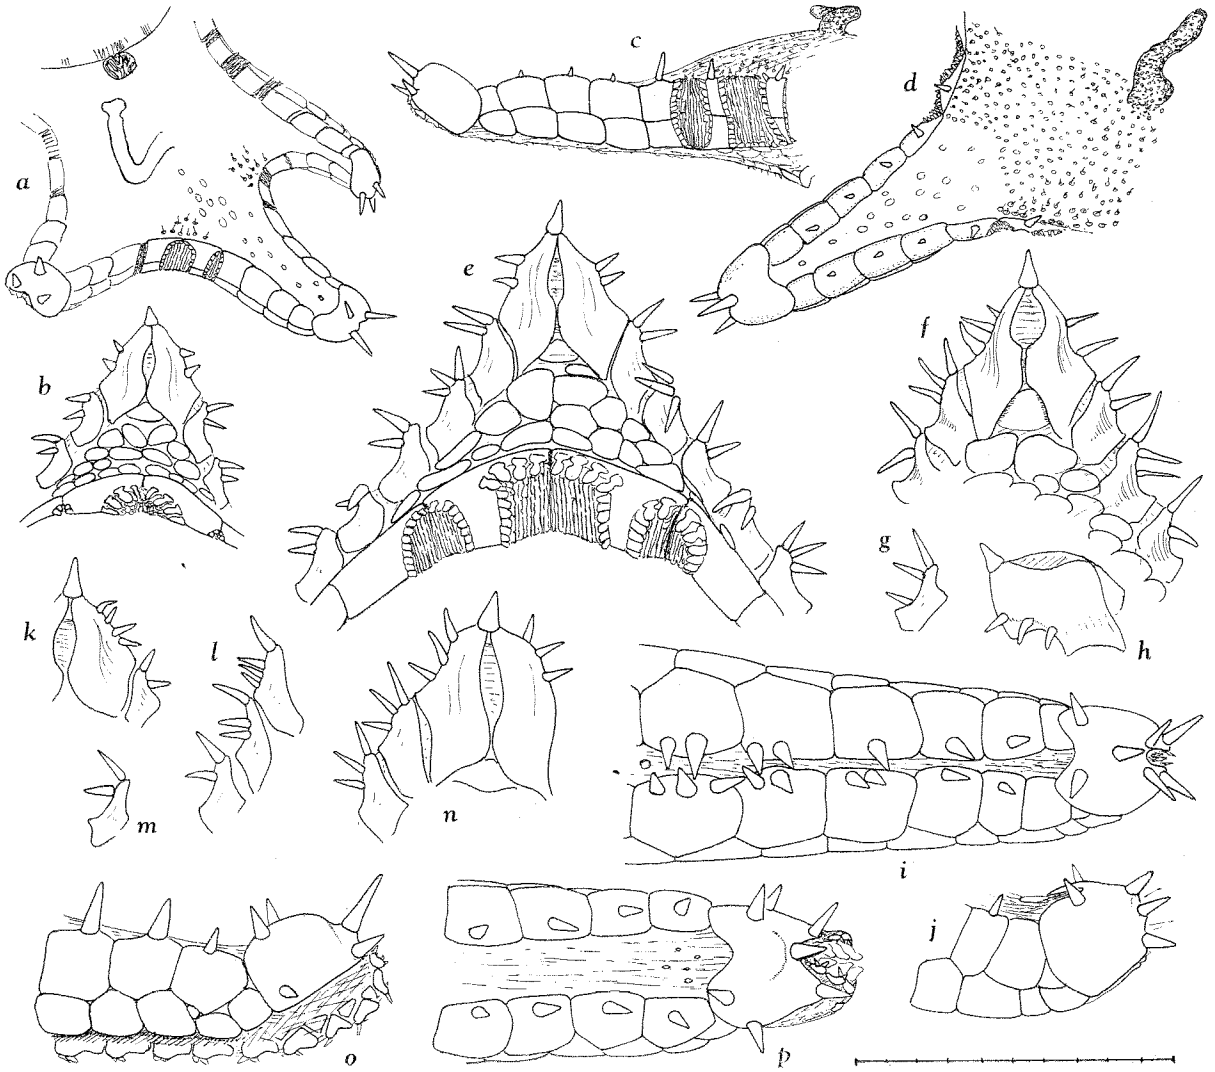

Fig. 28. *Eremicaster crassus*. St. 474. a-b) R/r 9/4 mm; b, part of ventral side in twice the usual scale. c-e) R/r 14/5.5 mm; e, part of ventral side in twice the usual scale. f-j) R/r 34/9.5 mm; g, adambulacral ossicle no. 3; i-j, arm in dorsal view and in lateral view. k) R/r 29/7 mm. l-p) R/r 37/11 mm; l-m, adambulacralia nos. 1-3 and 5 respectively; o-p, distal part of arm in lateral view and in dorsal view.
Scale: 10 mm (in b and e: 5 mm).

that with R/r 43/12.5 mm and 13-14 superomarginals, but also 15-16 in that with R/r 58/14 mm and 15-16 superomarginals, and only 11 in one with R/r 35/11 mm and 12 superomarginals.

In the present population, the juvenile specimen with R/r 9/4 mm (fig. 28*a*) still has no superomarginal spines developed. The other small one, R/r 14/5.5 mm (fig. 28*c, d*), has spines on all the superomarginals except the distalmost ones, but only those on the first and second superomarginals are well developed, the others are all yet rudimentary. As in the two other populations described, each superomarginal plate is usually provided with a single spine only, but in some specimens a varying number of the superomarginal plates carry 2 or 3 spines (in the usual longitudinal row), and in the specimen with R/r 43/12.5 mm there may be up to 5 and then more irregularly arranged spines on the more distal superomarginals. On the first superomarginals the spines may be only small, and in some cases apparently not developed at all, as e. g. in the specimen with R/r 37/11 mm.

The number of cribriform organs is 3 in each interradius already in the juvenile specimen, and it is also 3 in all the other specimens up to a size of R/r 43/12.5 mm; but in the single, very large specimen, with R/r 58/14 mm (pl. XII 8), there are 5 cribriform organs in each interradius. While the

three median cribriform organs are of the usual lamelliform structure, the supplementary outermost ones are rather papilliform. They are composed of up to 8 rows of papillae and are thus, though narrow, well marked.

The terminal ossicles in these specimens from south of Java are less conspicuous than in those from sts. 217 and 238 in the western part of the Indian Ocean. Four specimens, the three smallest and one with R/r 29/7 mm, have only the three typical terminal spines, whereas one with R/r 22/6.5 mm, and also all the remaining larger specimens, have at least 5 terminal spines, there being an additional proximal pair dorsally, with one spine to each side, or two pairs of dorsal spines proximally, and in a few cases further a small spine laterally to each side near the margin, adjacent to the inferomarginal plates, thus 7 spines in all (fig. 28*p*). In a specimen with R/r 34/9.5 mm there is also an extra pair of subterminal spines, and the terminal ossicles in this specimen thus bear 7 or 9 spines in all, depending on whether they are provided with one or two pairs of proximal dorsal spines (fig. 28*i,j*).

The dorsal armature in these specimens, except the smallest one, shows the same variation as described for the specimens from sts. 217 and 238, with the spinelets increasing in number with growth, but never spreading beyond the distal corner of the outermost cribriform organs, and with the arm bases and the arms provided only with spaced naked plates, which in some of the large specimens may reach a size of about 1 mm in diameter, but in other equal-sized specimens are at most 0.5 mm in diameter. All specimens have a distinct apical appendage. The juvenile specimen with R/r 9/4 mm shows radially on the disk fairly large circular spots, which may be interpreted as indicating the places of the embryonic plates, which, however, are now absorbed. In this specimen the dorsal spinelets are also still confined to the interradial area, near the margin. Two of the medium-sized specimens show papulae scattered over the main disk area. The specimen with R/r 37/11 mm has the gonad papillae observable in some interradii.

The adambulacral and oral armature is in about one-third of these specimens from st. 474 similar to what was described for the specimens from sts. 217 and 238 (i. e. with the aboral adambulacral spines and the lateral oral ones transformed into segmental papillae). The adambulacral segmental papillae are usually subcircular, but in one specimen they are very broad and with the distal squarely cut margin dentate. Segmental papillae may be found developed on the adambulacralia for almost the whole length of the arm. In about two-thirds of the specimens from st. 474 however, all adambulacral spines, and also the lateral oral ones, are acicular (fig. 28*b, e, f, n*), there being thus no so-called segmental organs formed at all. Usually there are only two adambulacral spines placed close together and diverging on the protruding adoral part of the furrow margin, but 3 spines to each adambulacral ossicle (especially of the more proximal ones) is more frequently occurring when the whole armature is spiniform, than when the aboral spine is modified as a segmental papilla (which also occupies more space on the ossicles than do the spiniform spines). A single specimen, R/r 37/11 mm, bears 4 spines on one of the first adambulacral ossicles. The number of adambulacral ossicles is e. g.:

R	Number of superomarginalia	Number of adambulacralia
9 mm	5	11
14 mm	6	14-15
34 mm	10	20
35 mm	12	21
43 mm	13-14	26
58 mm	15-16	30

In the specimen with R/r 37/11 mm the ambulacral furrow reaches just beyond the terminal ossicle.

The oral ossicles may show, at the tip of the combined pairs, only a minute spine, instead of the usual fairly large conical mouth-spine, or there may be two such minute spines, one on each ossicle. Proximally to the usual lateral oral spines, an additional slender spinelet may occur on the lateral corner of the ossicle. There are usually two lateral oral spines, but a few specimens have 3 spiniform spines laterally, at least on some of the oral ossicles, and a single specimen has 4 lateral spiniform spines on one of the oralia (on the others 3). A single oral ossicle is seen with only one lateral spine (in this case modified as a segmental papilla).

The ventrolateral plates are naked. The number of tangential rows e. g. is 6-7 in the specimen with R/r 43/12.5 mm.

Biological remarks:

One of the large specimens from st. 217 was found with female gonads which though almost emptied still contained a few eggs about 0.5 mm in diameter.

A dendrogate ascothoracid with nauplii larvae was found in a specimen with R about 40 mm.

Distribution:

Eremicaster crassus is known, besides from the type-locality in the mid-South Pacific, from four dredgings in the Indian Ocean: three off tropical East Africa and one south of Java (fig. 39). It has been found at depths from 3390 to 4271 m, on a bottom of red clay and globigerina ooze, and at temperatures of 1.2°-1.8°C. (In the eastern Pacific it is represented by a closely related form, *E. gracilis*).

Eremicaster gracilis (Sladen, 1883)
(E. crassus subspecies).

Non: *Eremicaster tenebrarius,* Macan 1938 *(= E. crassus).*

Sladen described his species *Porcellanaster gracilis* on the basis of a specimen taken by the Challenger in the South Pacific off Chile (st. 298: 34°07′S, 73°56′W, 4070 m, blue mud, 1.3°C.). R/r 10/4.5 mm; 8 subquadrangular superomarginal plates, usually with a dorsal spinelet; 3 lamelliform cribriform organs. Terminal ossicle fairly inconspicuous, with 3 spines. Dorsal side with spinelets in interradial bands; papulae present; a distinct apical appendage. Adambulacralia with 2 spines, the aboral one transformed into a segmental papilla on the proximal ossicles (the number of adambulacralia 13, judging from the figure). Oralia, besides the mouth-spine, with 2 as segmental papillae modified lateral spines. Naked ventrolateral plates.

It is evident that Sladen's *P. gracilis* is closely related to his *P. crassus*. Fisher (1907, 1911 p. 28) in connection with his discussion of the relationships of his own species *E. tenebrarius,* also suggests that *P. gracilis* is probably only a very young specimen of *P. crassus* "because the differences cited are such as would be expected in a young example". But when Fisher's own form *E. tenebrarius* is included in the considerations one may wonder, however, why he should connect *gracilis* with *crassus,* and not with his own *tenebrarius*. It is really impossible to point out any taxonomical characters distinguishing *gracilis* from *tenebrarius,* and the features which Fisher mentions as distinguishing his *tenebrarius* from *crassus* (primarily a greater number of superomarginals) are the same by which *gracilis* differs from *crassus*. Therefore the present author must conclude that Fisher's *E. tenebrarius* is identical with the form previously described by Sladen under the name of *P. gracilis*. But, as has been pointed out above (cf. also p. 145), this form differs only slightly from *crassus,* and perhaps is best regarded only as a zoogeographical subspecies (if to be kept distinct at all).

Fisher (1905) described his *Porcellanaster (Eremicaster) tenebrarius* on the basis of three specimens dredged by the Albatross off California (st. 4397: 200 miles off San Diego, 4016-4075 m, gray mud), and a few days later Ludwig published, under the name of *Porcellanaster waltharii,* a description of the same form based on 30 specimens collected by the Albatross in eight dredgings somewhat farther south, in the Panamic region (st. 3360: 6°17′N, 82°05′W, 3058 m, fine black and green sand, 2.4°C.; st. 3361: 6°10′N, 83°06′W, 2690 m, green ooze, 2.6°C.; st. 3374: 2°35′N, 83°53′W, 3334 m, green ooze, 2.4°C.; st. 3381: 4°56′N, 80°53′W, 3241 m, green mud, 2.1°C.; st. 3399: 1°07′N, 81°04′W, 3182 m, green ooze, 2.2°C.; st. 3400: 0°36′S, 86°46′W, 2418 m, globigerina ooze, 2.2°C.; st. 3414: 10°14′N, 96°28′W, 4082 m, green mud, 2.1°C.; and st. 3415: 14°46′N, 98°40′W, 3436 m, globigerina ooze, 2.2°C.).

That *P. waltharii* is the same as *E. tenebrarius* is noted by Fisher in 1907 p. 12. In 1911 Fisher, besides repeating the description (slightly emended) of the three original specimens of *E. tenebrarius,* described three additional specimens from a neighbouring locality (Albatross st. 4394: 200 miles off San Diego, 4132 m, gray mud), and 45 specimens from an Albatross dredging off southern Alaska (st. 2859: off Prince of Wales Island, 2870 m, gray ooze, 1.6°C.).

H. L. Clark in 1913 records a single *E. tenebrarius* from off Lower California (Albatross st. 5684: S.W. of Santa Margarita Island, 3219 m), and in 1920 he records 24 specimens from five Albatross dredgings in the eastern tropical Pacific off Peru (st. 4647:

4°33′S, 87°43′W, 3667 m, globigerina ooze, 1.9°C.; st. 4658: 8°30′S, 85°36′W, 4335 m, green mud, 1.8°C.; st. 4666: 11°56′S, 84°20′W, 4755 m, gray ooze, 1.6°C.; st. 4672: 13°11′S, 78°18′W, 5204 m, diatom ooze, 1.8°C.; and st. 4717: 5°11′S, 98°56′W, 3938 m, red clay, globigerina ooze, 1.8°C.).

In 1950 DJAKONOV recorded *Eremicaster tenebrarius* from east of Kamchatka, 4200 m. (In 1938 MACAN recorded and briefly described, under the name of *E. tenebrarius,* 24 specimens dredged by the Murray Expedition in the northwestern Indian Ocean, but, as demonstrated above, these are in reality representatives of *E. crassus).*

The type-specimen of FISHER's *E. tenebrarius* has R/r 37/12 mm (FISHER 1905) and 15 superomarginals (judging from the photo published by FISHER 1911 pl. 1, 1). In 1911 FISHER gives the size of two other Californian specimens as R/r 38/11 and 42/9 mm, and records the number of superomarginals as from 15 to 18-19 in large specimens. The single Californian specimen recorded by H. L. CLARK (1913) had R/r 25/8 mm and 10 superomarginals. Twenty of the specimens described from the Panamic region by LUDWIG in 1905 (under the name *waltharii)* had R/r in mm as follows, with the number of superomarginals added in parentheses: 10/4 (7), 12/5 (7), 13/6 (8), 14/5.5 (8), 17/7 (8), 18/7 (8), 24/8 (10), 28/9.5 (10), 31/11 (12), 32/11 (14), 36/13 (13), 38/12 (15), 41/15 (15), 43/13 (16), 46/14 (14), 48/15 (16), 50/15 (15), 54/16 (16), 56/17 (16), and 60/16 (20). LUDWIG also notes that 8 adambulacralia correspond to 6 marginalia in the median part of the arms of large specimens. One of the Alaskan specimens, which FISHER discusses in 1911, has R/r 22/6 mm, others R/r about 22/8 mm, and 12 or (judging from the photo pl. 1, 3) 11 superomarginals, and a small one has R/r 10/5 mm and 8 superomarginals. FISHER states that the number of superomarginal plates in this Alaskan material is up to 17, but does not say how large the specimens are. The Peruvian specimens recorded by H. L. CLARK (1920) had R up to 45 mm.

The characters of *E. tenebrarius,* according to FISHER's descriptions, are as follows: Superomarginals subquadrate, typically with an erect spine on their upper edge, sometimes 2 or even 3 spines, or no spines at all (as in 33 of the 45 specimens from the single Alaskan dredging, which, however, are probably all young ones with R/r from 10/5 to on an average 22/8 mm?). Inferomarginals lower than superomarginals. Terminal ossicle as large as two last superomarginals, strongly concave proximally, in the type-specimen with 5 spines, a distal terminal one, a pair of subterminal ones, and one to each side dorsally. (In the Alaskan specimens recorded, and in juveniles from the Panamic region, only 3 terminal spines). Dorsal side with small rounded plates, those of disk with single spinelets. A distinct apical appendage. Papulae in disk area. Adambulacralia with 2 (proximally perhaps 3) furrow spines, the aboral one transformed into a segmental papilla (in the type for some length of the inner half of the arms, in other specimens for almost the whole length of the arms, and in an Alaskan specimen with R/r 10/5 mm only on the two or three most proximal adambulacralia). Oral ossicles, besides the mouth-spine, with 3 lateral oral spines, the proximal one a slender, curved spinelet, the two others transformed into segmental papillae. (Other specimens have only the two segmental papillae laterally on the oralia). Ventrolateral area with naked elliptical plates. (Number of superomarginalia in relation to that of adambulacralia, according to LUDWIG, e. g. 3/4).

The Galathea material:

A large number of specimens of *Eremicaster* referable to the form *gracilis* (syn. *tenebrarius)* were collected in a dredging off Costa Rica, in the region of the eastern tropical Pacific from where the form has been recorded repeatedly previously. They were of a whitish colour with the filled stomach showing greyish blue through the integument.

St. 716: 9°23′N, 89°32′W, 3590 m, 2.0°C., dark muddish clay. 86 specimens.

The specimens range in size from R/r about 8/4 to about 57/16 mm, and thus the series includes specimens as small as any one hitherto recorded as well as specimens of about the known maximum size. The size of the individual specimens and their number of superomarginal plates, for some also the number of adambulacral ossicles, are recorded in the following survey. Part of the material is in a rather poor state, so sometimes the length of r could not be stated. (Incidentally, the figures of r should always be regarded with some caution, especially in the small specimens, since it can never be measured exactly).

R/r in mm	Number of superomarginalia	Number of adambulacralia

32-47	17
43-52	18
43-56	19
48-56	20
50-57	21
52-57	22
57	23

The superomarginal plates have the upper adoral corner rounded, and may be subquadrate, usually slightly longer than high, but more often are subrhomboid, with the adoral vertical margin convex and the aboral margin concave, sometimes even rather triangular, with the adoral and dorsal margins forming a continuous rounded contour. It usually looks as if the superomarginals markedly overlap each other in adoral direction, while they actually do so only very slightly or also meet edge to edge. The superomarginals are always arranged in regular series (fig. 29 *d, i, s*). The juvenile specimen with R 8-9 mm has yet only small superomarginal spines, and apparently the distal 3-4 superomarginals are still unarmed. All the other specimens bear

spines on all the superomarginals, typically one spine to each plate, only very exceptionally some plates may bear 2 spines. The spine on the second superomarginal plate is usually the largest, and the other spines decrease in length gradually towards the tip of the arms. In the larger specimens all superomarginal spines look subequal at a cursory glance. The spine on the first superomarginal plate is often only small, and sometimes apparently wanting, as in a specimen with R/r 18/7 mm, but it may also be fully as long as the second spine, as e. g. in a specimen with R/r 43/13 mm, measuring here about 3 mm in length. The number of inferomarginals is the same as, or one more than that of superomarginals.

The cribriform organs number 3 in each interradius in all the specimens. They increase in width with growth so that they almost coalesce in the large specimens.

The terminal ossicle is about half as high as broad, and forms an inconspicuous termination of the arm tip. It bears typically 3 or 5 conical spines, a distal terminal one, and a pair of slightly smaller subterminal ones (fig. 29*l*), and possibly an additional pair of proximal dorsal ones, one spine to either side of the proximal notch (fig. 29*s, t*). Specimens as large as R/r 55/14 mm may have only 3 spines on each terminal ossicle; and specimens as small as R/r 20/6 mm may have terminal ossicles with 5 spines, A single specimen with R/r 48/12 mm has two pairs of subterminal spines and thus 7 terminal spines in all. In a few specimens there are 2 diverging distal terminal spines side by side, instead of the usual unpaired one, thus 6 terminal spines in all. And one specimen, R/r 50/16 mm, has, besides four normal terminal ossicles with 5 spines, one on which not only the usual distal terminal spine is replaced by 2 diverging ones, but also the proximal dorsal spine to one side reduplicated, and further the subterminal spine to the same side trebled; thus this terminal ossicle is provided with 9 spines in all.

The central and interradial areas of the disk, as far as to a line connecting the distal corners of the outermost cribriform organs, is armed with small plates with a single spinelet each, mainly rather spaced, but in a small central area forming a close pavement (some plates here are apparently without spinelets). A distinct apical appendage armed with very minute plates is always present.

In contracted specimens the superomarginals lie like a roof over the arms, and only a narrow strip of wrinkled skin separates the opposite series to the terminal ossicle. In well expanded specimens the superomarginal plates form a vertical margin to the arms, in the whole length of which there is then a subequally broad stretch of a thin dorsal integument with scattered small unarmed plates, up to 0.5 mm in diameter. Papulae were observable in some specimens, on the main area of the disk, and in about the same number as the spiniferous plates. The madreporic body is subcircular, with the striae stretching across in radial direction. Gonad papillae were seen in some specimens, close to the distal corner of the first superomarginal plates.

The adambulacral armature consists for the proximal half or more of the arms of an aboral segmental papilla and an adoral acicular spine. Exceptionally there are 2 adoral acicular spines besides the aboral papilla (fig. 29*r*). Distally the adambulacral armature is composed of 2, or exceptionally 3 acicular spines.

The armature of the oral ossicles generally consists, besides of the conical mouth-spine, of 2 lateral, as segmental papillae modified spines (fig. 29*g*). Some oral ossicles, exceptionally all in a specimen, are provided with 3 lateral segmental papillae (fig. 29*e*). On the proximal lateral corner of the oralia there may occur a usually small, but occasionally fairly large spine (or, very exceptionally, 2 spines side by side). A single oral ossicle was found with an additional spiniform oral spine distally to the segmental papillae (fig. 29*h*).

In the ventrolateral area there is a close pavement of generally naked plates. Two of the present 86 specimens, however, are noteworthy on account of being provided with a few, or several ventrolateral spinelets, and as this is very unusual, these specimens will be described in more detail below.

Description of two specimens of *Eremicaster gracilis* with ventrolateral spines. (Fig. 29*u-æ*).

One specimen (fig. 29*u-z*) has R/r 46/11 mm; 22 superomarginalia (with spines); 3 terminal spines; dorsal armature as usual; 26-27 adambulacralia, proximally with the usual armature of an adoral spine and an aboral segmental papilla. Oralia with 2 (in one case 3) lateral segmental papillae, and in a few cases also 1-2 proximal lateral spinelets. Ventrolateral plates arranged as usual, but a number of the more distal ones each with a single conical spine (or spinelet), about 10 in each interradius (fig. 29*x, y, z*). The specimen has two of its arms in regeneration, which shows that it has been subject to damage in life, and perhaps the development of ventrolateral

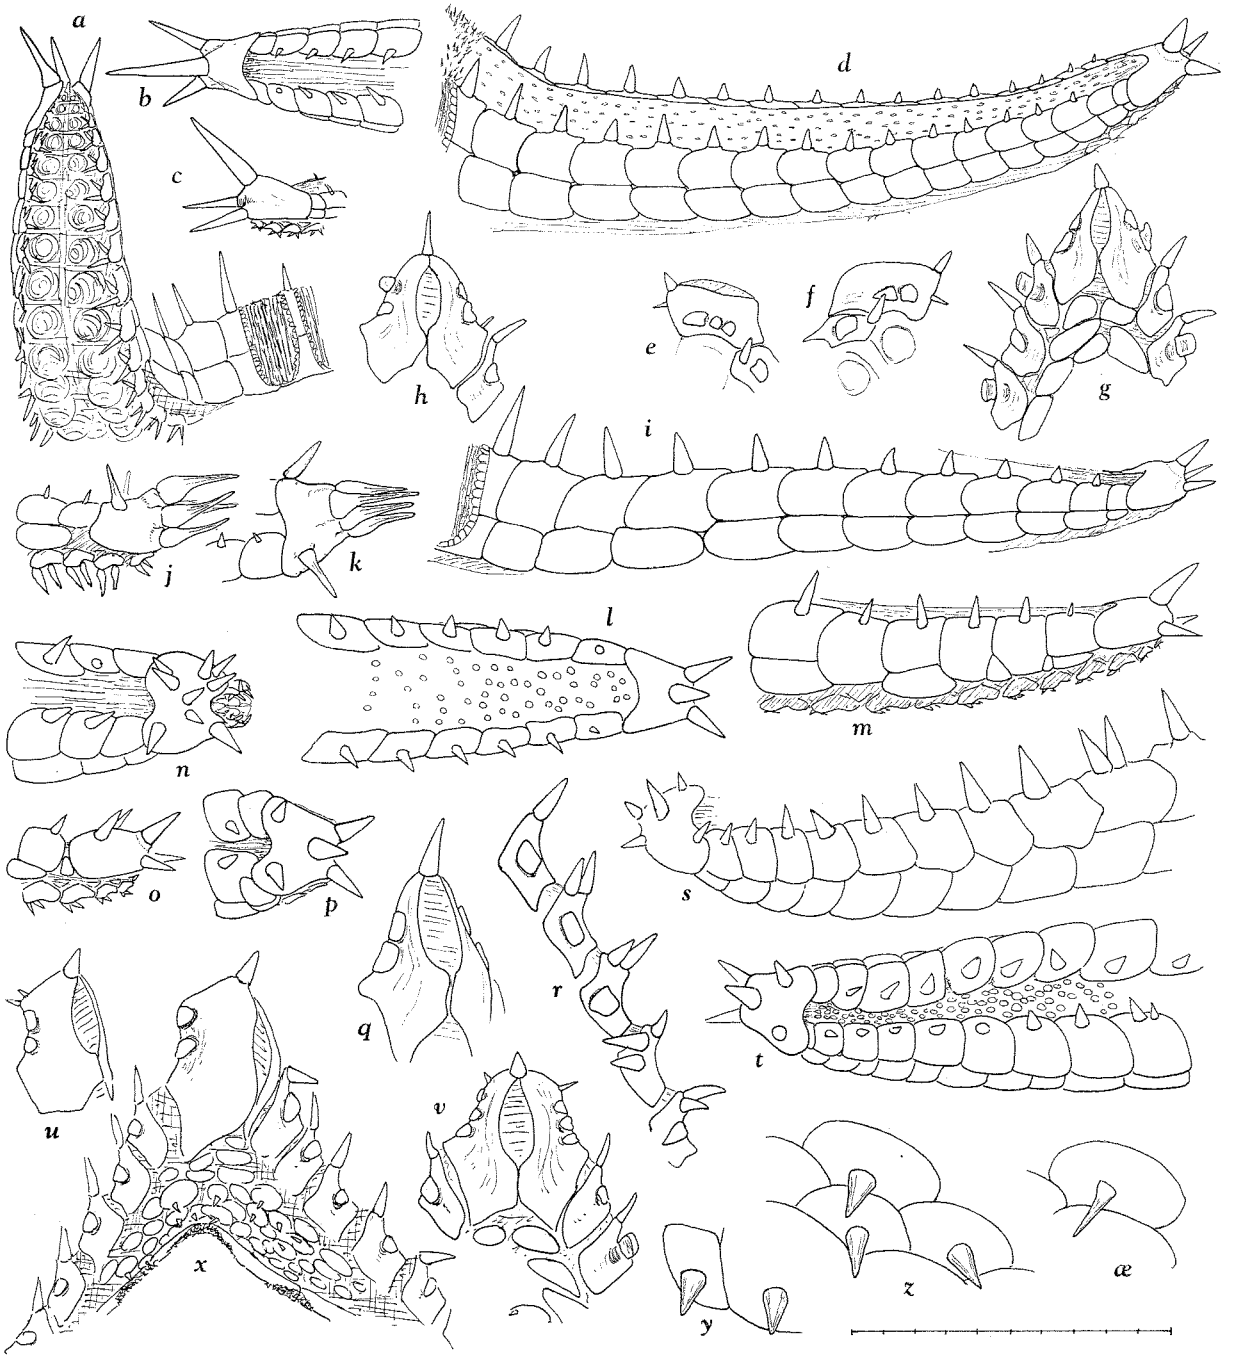

Fig. 29. *Eremicaster gracilis*. St. 716. a-c) R/r 22/6 mm, three arms in different view. d-g) R/r 32/10 mm; e-g, three jaws in different views. h-i) R/r 34/11 mm. j-k) R/r 48/12 mm, terminal ossicle in side view and in dorsal view. l-m) R/r 50/11 mm, arm in dorsal view and in side view. n) R/r 10/16 mm. o-p) R/r 52/12 mm, two terminal ossicles in side view and in dorsal view respectively. q) R/r 51/13 mm. r) R/r 52/14 mm, adambulacralia nos. 6-10. s) R/r 51/15 mm. t) R/r 55/15 mm. u-z) R/r 46/11 mm; u-v, different jaws; y-z, two groups of ventrolateral spinelets, in four times the usual scale. æ) R/r 46/15 mm, ventrolateral spinelet in four times the usual scale.
Scale: 10 mm (in y-æ: 2.5 mm).

spines is caused by irritation of the integument. The specimen is also infested with a commensalistic hydroid.

The other specimen has R/r 46/15 mm; 18 superomarginalia, with rather broad and flattened spines; 5 terminal spines; dorsal side typical; adambulacral and oral armature also typical. Ventrolateral plates in the typical arrangement, but in three of the interradii with 1 to 3-4 scattered plates each with a single slender spinelet (fig. 29 *æ*).

The ventrolateral spines or spinelets in these two specimens are very unlike each other in general appearance (cf. fig. 29*z* and 29*æ*). Ventrolateral spines probably may be easily lost in the preserved specimens, and so perhaps also other of the specimens had ventrolateral spines in life. On the other hand, the first mentioned of the two spiniferous specimens is in a poor state, rather distorted and torn, but nevertheless still with its ventral spine-armature preserved.

These two specimens agree in the possession of a ventrolateral spine-armature with *E. pacificus,* but they are easily distinguished from this species in e. g. the shape of the terminal ossicles and the appearance of the outer series of covering papillae in the cribriform organs. The ventral spine-armature in *E. pacificus* has also a different general appearance.

Biological remarks:

Supposedly ripe eggs were found in the gonads of a couple of specimens with R/r 48/13 and 50/13 mm. They are slightly oval in shape and have a greater diameter of 0.5-0.6 mm. (LUDWIG in 1905, p. 97, recorded 0.6 mm large eggs from a specimen of his *Porcellanaster waltharii (= E. gracilis)* with R 42 mm).

One specimen with R/r 47/15 mm appears to be infested with an ascothoracid, since in one radius of the disk there is a pair of close-set holes surrounded by a thickened wall of the integument.

Four specimens, the one with R/r 46/11 mm and ventrolateral spines, and three others with R/r 22/6, 47/15 and 50/15 mm respectively, are all infested with a commensalistic athecate hydroid, in a number of one to about half a dozen individuals on each sea-star, mostly attached to the ventral side, round the mouth on the peristome proximally to the series of tube-feet, or for instance on the jaws, but one hydroid is also found on the dorsal side close to the fifth superomarginal plate.

Distribution:

Eremicaster gracilis (syn. *tenebrarius)* is up to the present day collected in 18 dredgings in the eastern Pacific, off the American coast from northern Chile to southern Alaska, and is further recorded from the recent Russian explorations of the deep-sea near Kamchatka (fig. 39). It has been found at depths between 2690 and 5204 m, mainly on a bottom of mud (grey, blue, green) or globigerina ooze, but also on diatom ooze, sand and muddish clay. The temperatures recorded range from 1.3° to 2.6°C.

Nec: *Eremicaster pacificus,* MADSEN 1956 pp. 26-27. *(= E. vicinus).*

This species was described by LUDWIG (1905) from 21 specimens collected by the Albatross in seven dredgings in the eastern tropical Pacific in the Panamic region (st. 3360: 6°17′N, 82°05′W, 3058 m, fine black and green sand, 2.4°C.; st. 3362: 5°56′N, 85°11′W, 2149 m, green mud, sand and stones, 2.7°C.; st. 3376: 3°09′N, 82°08′W, 2070 m, globigerina ooze, 2.4°C.; st. 3392: 7°06′N, 79°40′W, 2323 m, hard Rhabdamnina bottom, 2.4°C.; st. 3400: 0°36′S, 86°46′W, 2418 m, globigerina ooze, 2.2°C.; st. 3411: 0°54′N, 91°09′W, 2174 m, globigerina ooze, 2.4°C.; and st. 3415: 14°46′N, 98°40′W, 3436 m, globigerina ooze, 2.2°C.).

FISHER in 1911 added the record and description of 6 specimens from three Albatross dredgings in the Bering Sea and in the eastern North Pacific, off southern Alaska and off Washington (st. 3603: Bering Sea, between Pribilof and Umnak Islands, 3239 m, brown ooze; st. 2859: off Prince of Wales Island, southern Alaska, 2870 m, 1.6°C.; and st. 3075: off Washington, 1571 m, green mud). H. L. CLARK in 1913 recorded 11 specimens from three Albatross dredgings west of Lower California (st. 5673: off Point San Tomas, 1994 m; st. 5691: off Point San Tomas, 1588 m, 2.9°C.; and st. 5692: off Point San Tomas, 1968 m, 2.8°C.). And in 1920 H. L. CLARK finally recorded 2 specimens dredged by the Albatross at two stations off Peru (st. 4647: 4°33′S, 87°43′W, 3667 m, globigerina ooze, 1.9°C.; and st. 4649: 5°17′S, 85°20′W, 4088, grey mud, 1.9°C.

(The present author formerly believed that LUDWIG's *E. vicinus* of 1905 was a form of *E. pacificus,* and under this latter name recorded (MADSEN 1951, 1956), from the Swedish Deep-Sea Expedition and the Galathea Expedition, some specimens which, as was also stated in the text, conformed to the description of *P. vicinus. Eremicaster vicinus,* however, is now recognized as a distinct species, cf. below).

LUDWIG (1905) gave the size of 10 of his 21 original specimens as follows, R/r in mm with the number of superomarginals added in parentheses: 14/7 (7), 15/7.5 (6), 16/8 (6). 17/8 (7), 19/8 (8), 22/10 (8), 23/10 (8), 24/12 (8), 26/12 (9), and 28/11 (9). The characters of his material are: Superomarginals each with an erect dorsal spine; always 3 well developed cribriform organs of a lamelliform structure. Terminal ossicles with 5 or 7 spines, viz. one or two proximal pairs besides the usual 3 distal spines. Dorsal side of disk centrally and interradially with small plates, each with a spinelet, and arm bases and arms with spaced small naked plates. A distinct apical appendage. Papulae in main disk area. Adambulacralia with diverging acicular furrow spines (in median part of arm 8 adambulacralia corresponding to 6 inferomarginalia). Oralia with 2-4, usually 3, acicular lateral marginal spines, besides the common conical mouth-spine. Ventrolateral plates each armed with a short spinelet.

One of the six specimens recorded by FISHER (1911) has R/r 21/10 mm; 8-9 superomarginals, with 1 (2) spines; terminal ossicles, besides the usual 3 spines, provided with 2-5 pairs of proximal dorsal spines (lacking, however, in a small specimen); main part of disk with spaced spinelets (occasionally also 2-3 isolated spinelets on outer part of arm); an apical appendage; adambulacralia with 2 sharp spinelets; oralia with an acicular mouth-spine, common to the combined pair of oralia, and 2-5 similar lateral spines; ventrolateral plates with spinelets similar to the dorsal ones.

H. L. CLARK (1913) records R in his 11 specimens as ranging from 8 to 24 mm. The specimen with R 8 mm had 5-6 superomarginalia, most of them with a spine, and 8-9 adambulacralia. The two specimens recorded by CLARK in 1920 had R 15 and 22 mm.

The characters which should distinguish *E. pacificus* from *E. crassus* and *E. gracilis (tenebrarius)* are firstly the presence of ventrolateral spinelets, and secondly that the furrow spines are never modified as segmental papillae. However, these characters alone would not be sufficient for distinguishing *E. pacificus* with certainty. Thus in populations of *E. gracilis* specimens may occasionally occur which have ventrolateral spines, though in the cases known conical or acicular, whereas those in *E. pacificus* are rather terete. And in populations of *E. crassus* there may be many specimens in which all the adambulacral and oral spines are spiniform, none of them being modified as segmental papillae.

Through the courtesy of dr. *Deichmann* of the Museum of Comparative Zoology, the present author has been enabled to examine one of H. L. CLARK's specimens from the Albatross st. 5691. This re-examination has shown that further differences distinguishing *E. pacificus* from *E. crassus* and *E. gracilis*, may be e. g. the shorter, broader and proximally more deeply concave terminal ossicle and possibly also a more complete dorsal pavement of plates in the arms, a character, however, which may be individually variable. The shape of the single papillae of the covering outer series in the cribriform organs affords a distinguishing character too, being very large quadrangular ones in *E. pacificus*, but not especially conspicuous in the other species.

Distribution:

Eremicaster pacificus is known from fourteen dredgings in the eastern Pacific, from the Bering Sea to Peru (fig. 40), in depths of 1571 to 4088 m, on a bottom of sand or mud or globigerina ooze, and at temperatures ranging from 1.6° to 2.9° C. It has further been taken in the western North-Pacific (the Bering Sea) by the Vitjaz.

Eremicaster vicinus (Ludwig, 1907)

Eremicaster pacificus, MADSEN 1951 pp. 76-78, fig. 1. (Non *pacificus* Ludwig).
Eremicaster pacificus, MADSEN 1956 pp. 26-27. (Non *pacificus* Ludwig).

LUDWIG in 1907 gave a preliminary description of this species, and of a separate variety, based on some specimens collected by the Albatross expeditions in the eastern tropical Pacific (off Peru); and H. L. CLARK in 1920 briefly dealt with the same material and published photographs of one specimen. The type-locality of *P. vicinus* (according to H. L. CLARK) is the Albatross st. 4670 (12°08'S, 79°02'W, 5869 m, fine dark brown mud, 1.9° C.), and specimens by LUDWIG registered as *P. vicinus* var. *inermis* were taken at the same station and at the neighbouring st. 4672 (13°12'S, 78°18'W, 5204 m, fine, dark, brown mud, 1.8° C.). H. L. CLARK, who does not keep the variety distinct, re-

cords 44 specimens from the former station and 2 specimens from the latter.

The specimens described of *E. vicinus* (inclusive of the variety *inermis,* which is distinguished only by the lack of superomarginal spines) range in size from R 9.5 mm over R/r 17/8, 21/10 (the type of *vicinus)* and 24/10 mm to R 32 mm. The number of superomarginalia is 4 in the small specimens, 7 in the medium-sized ones, and 10 in the large ones. Superomarginals of arm angle, at least first two, without spines, and sometimes all superomarginals naked (var. *inermis),* but otherwise the superomarginal plates of the arms with single spines. Three cribriform organs. Terminal ossicles with 3 spines. Dorsal side with scattered spinelets each on its own small plate. Adambulacralia with 2 spines. Oralia with 1-2 minute lateral spines besides the common mouth-spine. Ventrolateral plates naked.

LUDWIG noted that his new species *P. vicinus* was distinguished from the otherwise closely related *P. pacificus,* firstly by the complete absence of ventrolateral spines, secondly by having only 1 (or rarely 2) minute lateral oral spines, and thirdly by the absence of spines on the superomarginals of the arm angle; and LUDWIG further notes that the terminal ossicles bear ventrally only one pair of spinelets, instead of two pairs. Taken separately these differences are not very important in taxonomical respect. The absence of ventrolateral spines seems to offer the most reliable distinguishing character, but the presence or absence of ventrolateral spines is individually variable in e. g. *Porcellanaster cæruleus* and also in the above described population of *Eremicaster gracilis.* The absence of superomarginal spines in the arm angles is only a poor character, and the same applies to the low number of lateral oral spines. LUDWIG himself recorded the number of lateral oral spines in his *P. pacificus* as 2-3, rarely 4. From LUDWIG's own description of *P. pacificus* it also appears that a single pair of subterminal spines is the usual. The evidence drawn from these considerations therefore supports FISHER's conclusion, 1911 p. 30, that *vicinus* "is insecurely separated from *pacificus*".

H. L. CLARK in 1920, when dealing with LUDWIG's material, maintained *E. vicinus* as a separate species and noted that he did not think that FISHER would consider *E. vicinus* insecurely separated from *pacificus* if he had compared specimens. And then continues: "Besides the absence of actinal interradial spinelets, *vicinus* has two characteristics which easily separate it from *pacificus.* One of these is found in the adambulacral spines, which are very small (short and slender) and are placed close together at the adoral end of the plate, while the other and more conspicuous is in the spinulation of the oral plates, which have only one, or sometimes two minute conical spinelets near the center of the margin. While the abactinal surface of *vicinus* is thus indistinguishable, by any constant character, from that of *pacificus,* the oral surface is separable at a glance."

The differences stated by CLARK, however, do not at all prove the specific validity of *E. vicinus.* FISHER was a most reliable taxonomical observer, and so his statement of *E. vicinus* being insecurely separated from *E. pacificus* supported the present author in recording (1951) under the name of *E. pacificus,* 2 specimens dredged by the Swedish Deep-Sea Expedition in the tropical Atlantic (st. 329: about 9°44′N, 26°25′W, 5610-5600 m, calcareous red clay, 2.4° C.), though these specimens, as stated in the text, agreed with the description of LUDWIG's *vicinus.* In 1956 the present author further recorded under the name of *pacificus* 9 specimens from two hadal dredgings by the Galathea in the Sunda Trench and in the Kermadec Trench respectively, which too – as stated in the text – agreed with LUDWIG's description of *vicinus* var. *inermis.*

The study of the large Galathea-material of *Eremicaster,* and the re-examination of a specimen of *E. pacificus* from the Albatross collections, besides a re-examination of one of LUDWIG's original specimens of *vicinus* (from Albatross st. 4670) – also through the courtesy of Dr. DEICHMANN – have, however, induced the present author to amend his former view on *E. vicinus.*

LUDWIG's *vicinus* is undoubtedly a distinct form, and probably of specific rank, although related to *E. pacificus.* It is distinguished from *E. crassus* and *E. gracilis* by having the arms and arm bases (outwards of the outermost cribriform organ) more or less completely paved with fairly large naked plates, considerably larger than the spine-bearing ones of the disk area; by having a central area on the disk paved with plates somewhat larger than those of the main part, by lacking a distinct apical appendage, though, according to CLARK's photo fig. 7 pl. 2, possibly with an apical cone; and further by having a weaker furrow armature. What distinguishes *E. vicinus* from *E. pacificus,* is the shape of the terminal ossicle: less broad and with only 3 spines (the number of spines on the terminal ossicle, however, is a very poor character); the appearance in the cri-

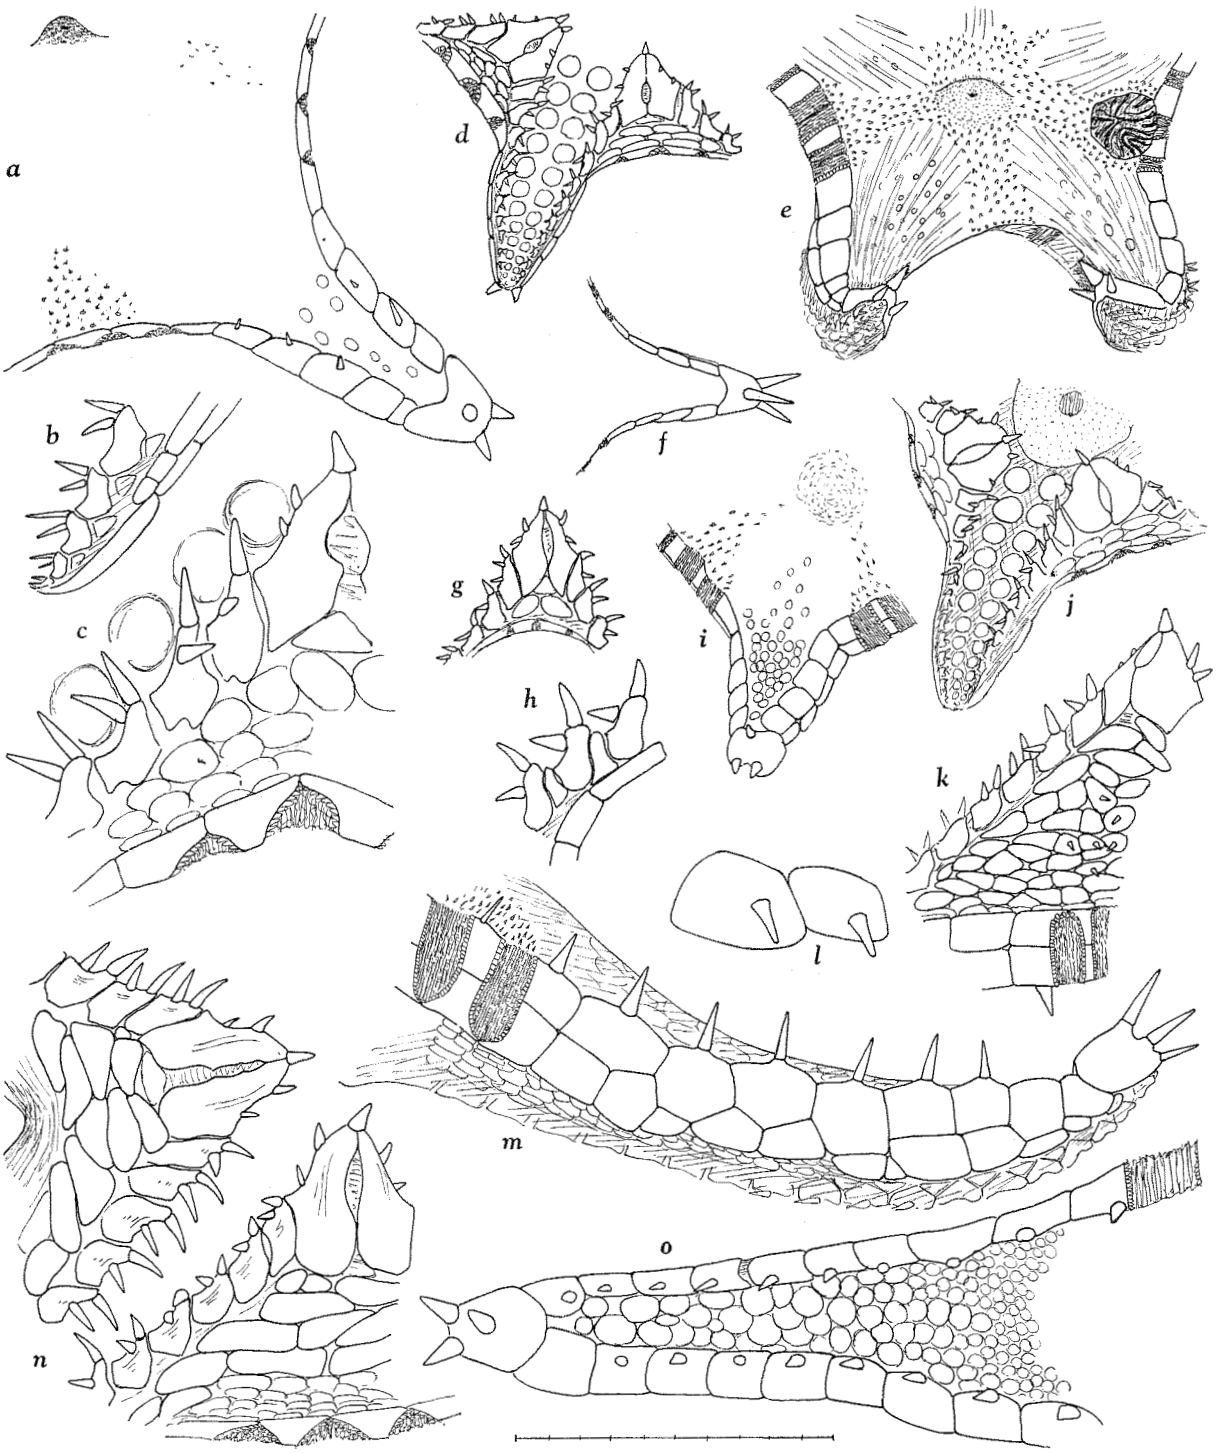

Fig. 30. *Eremicaster vicinus*. a-c) Swedish Deep-Sea Expedition st. 329; b-c, distal adambulacralia and part of ventral side, in twice the usual scale. d-j) Galathea st. 465. d) R/r 11/4.5 mm. e) R/r 14/5-6 mm. f) R/r 8-10/4 mm. g-h) R/r 12/5 mm; h, adambulacralia nos. 4-6 in twice the usual scale. i-j) R/r 11/4.5 mm. k-o) Galathea st. 650. k-m) R/r 25/8 mm; l, ventrolateral spinelets in four times the usual scale. n-o) R/r 30/9 mm; n, part of ventral side, showing two jaws. Scale: 10 mm (in b-c, and h: 5 mm, in l: 2.5 mm).

briform organs of the papillae in the outer covering series: not especially enlarged; and the absence of a distinct apical appendage, at least in specimens of some size. Also the usually naked ventrolateral plates may distinguish *E. vicinus* from *E. pacificus*, but as will appear from the re-description of the Galathea specimens, some specimens of *E. vicinus* may show scattered ventrolateral spinelets.

The two specimens which were described from the Swedish Deep-Sea Expedition in the Atlantic, have R/r 18-19/8 (fig. 30*a-c*) and 19-20/8 mm; 6-7 and 8-9 superomarginalia; and both of them 13-14 adambulacralia. Superomarginal plates of arms with spines, but those in arm angle naked. Three terminal spines. One of the specimens in one interradius has 4 instead of the usual 3 cribriform organs. Dorsal side of disk with small plates carrying single spinelets, and with a small apical cone; spaced naked plates in the arms. Adambulacralia with 2 small furrow spines. Oralia with 2 small distally placed lateral spines, besides the common mouth-spine. Ventrolateral plates naked.

The Galathea material:

Specimens of *Eremicaster vicinus* were collected, as the only porcellanasterids, in two of the hadal dredgings undertaken during the Galathea Expedition, in the Java Trench and in the Kermadec Trench respectively.

St. 465: 10°20′S, 109°55′E, 7000-6900 m, 2.1°C. 5 specimens.

St. 650: 32°20′S, 176°54′E, 6620-6730 m, 1.3°C., brown clay with pumice. 3 (or 4) specimens.

(The depths recorded in 1956 had to be slightly revised).

The specimens from st. 465 in the Java Trench are juveniles, ranging in size from R/r ab. 8-10/4 to 14/5-6 mm.

R/r in mm	Number of superomarginalia	Number of adambulacralia
about 9/4	5	9(-10)
11/4.5	5-6	10-11
11/4.5	6	12
12/5	6	9-10
14/5-6	6	12

The two first-mentioned specimens show the juvenile character of a close pavement of unarmed perforated plates dorsally, these embryonic plates being the only dorsal skeleton. In the third specimen mentioned, scattered spinelets occur interradially (fig. 30*i*), and in the two last-mentioned and slightly larger specimens there are distinct interradial bands of spinelets. The largest specimen is provided with a distinct apical cone (fig. 30*e*). (And it certainly appears as if there is a central pore in this cone?). The superomarginals are subquadrate and are all unarmed (fig. 30*e, i*). Three cribriform organs. Terminal ossicles with 3 spines. Adambulacralia with 2 spines (fig. 30*d, g, h, j*). Oralia with 1-2 (3) small lateral spines, besides the common mouth-spine (fig. 30*d, g, i*). Ventrolateral plates naked (fig. 30*d, g*).

The three specimens from st. 650 in the Kermadec Trench are fairly large ones (a fourth much damaged specimen of sub-equal size was found in the meshes of the trawl after the attempted dredging at st. 656 but, since in all probability bottom was not reached, must have been overlooked when the trawl was emptied after the haul at st. 650).

R/r in mm	Number of superomarginalia	Number of adambulacralia
25/8	9/10	18
29/10	11	29
30/9	11	20

The superomarginals are subquadrate or slightly longer than high, and the inferomarginals of the arms are not much lower than their superomarginal companions. The superomarginals each bears a single slender dorsal spine, except sometimes the last ones, and possibly also the first one. The spine on the first superomarginal plate at least is always smaller than the others (fig. 30*m*). The 3 cribriform organs all show the characteristic subquadrate covering papillae. The terminal ossicles bear 3 spines in two specimens (fig. 30*o*), but 5 in the third, here being two pairs of subterminal ones (fig. 30*m*). The median and interradial area of the disk is armed with close-set small rounded plates each with a spinelet, and there are scattered papulae. There is an apical cone, but nothing like a distinct apical appendage as in the other forms of *Eremicaster*. In the arms and the arm-bases, delimited from the disk by a line connecting the distal corners of the outer cribriform organs, there is a close pavement of plates (fig. 30*o*), somewhat larger than the spiniferous ones. The adambulacralia bear 2 spines. The oralia have 2 lateral spines besides the mouth-spine (fig. 30*n*). The ventrolateral plates are usually naked, but the re-examination now undertaken revealed that one of the specimens has single conical spinelets on a small number of the median ventrolateral plates in one interradius (fig. 30*k, l*).

The occurrence of ventrolateral spines in one of these specimens confirms that the possession of these is of doubtful taxonomic value, and reduces the difference between *E. vicinus* and *E. pacificus*. But, as mentioned above, e. g. the different shape of the terminal ossicles, the different development

of the apical prominence, and the different appearance of the outer papillae in the cribriform organs separate the two forms.

The presence of a close pavement of fairly large plates in the arms of the Galathea specimens is a character which they share with the original specimens of *vicinus,* as has been ascertained by a re-examination of one of these, and as can be seen on the photograph published by H. L. CLARK (1920). Such a close armature is not found, however, in the Atlantic specimens from the Swedish Deep-Sea Expedition. Apparently the dorsal armature of plates in the arms of *E. pacificus* may be subject to a similar individual variation, and thus the feature can hardly be used in separating an Atlantic form of *vicinus* from a Pacific form.

Distribution:

Eremicaster vicinus has been found in a small number of dredgings in the deeper parts of the three great oceans (fig. 40), one in the mid-Atlantic, one in the Indian Ocean in the Java Trench, and a few in the Pacific, one of which in the Kermadec Trench, and the two others off Peru. Further it has recently been dredged in the North Pacific by the Vitjaz. The form is recorded taken at depths from 5204 to 7245 m, on mud and calcareous clay, and at temperatures between 1.3° and 2.4°C.

Apparently *Eremicaster vicinus* is the hadal representative of *Eremicaster pacificus.*

Sidonaster Koehler, 1909

Type-species: *Sidonaster vaneyi* Koehler, 1909.

Diagnosis:

Porcellanasterids with opposite superomarginals separate in whole arm length, and each with a dorsal spinelet. A mid-interradial suture. A single cribriform organ of a papilliform structure. A single proximal, enlarged mouth-spine, common to both oralia forming a jaw. Terminal ossicle distal to arm end, subcrescentic, much broader than long.

Description:

The general appearance of this genus is the same as that of *Porcellanaster* s. str., except for the shorter terminal ossicle and for the larger and papilliform cribriform organ. It may further be distinguished from *Porcellanaster* by the relatively larger (and hence in relation to length of R fewer) adambulacralia (and podia).

The single papilliform cribriform organ is very large, and with the calcareous papillae longer and more slender than in any other porcellanasterid. The rows of covering papillae extend from one outer dorsal corner continuously around the organ along the lateral and ventral side to the other dorsal corner. The first superomarginal plate, with the cribriform organ, is very much larger, higher and longer than the following ones, which are subquadrate, but with the adoral dorsal corner rounded. The superomarginals overlap with their curved adoral end more or less distinctly the aboral end of the preceding plate. All the superomarginals are armed with an erect dorsal spine of a length of up to about $1^1/_2$ times the height of the plate, and possibly with one or two accessory spinelets. The inferomarginals are less than half as high as their superomarginal companions. The terminal ossicle is deeply concave adorally and very broad in relation to its length (subcrescent-shaped), it carries 5-7 subequal spines, a distal terminal one, a pair of subterminal ones, and proximally on the dorsal surface 1-2 additional spines to either side. The disk is interradially armed with spinelets, each on its own small plate, and spinelets may occur over the whole main disk area to a line connecting the distal corners of the first superomarginals. (LIEBERKIND in 1932 p. 293 mentioned as a further character, distinguishing *Sidonaster* from *Porcellanaster* and *Eremicaster,* the occurrence in the dorsal integument of scattered calcareous rods besides the usual perforated plates, claiming it for certain that these rods really were found there and had not been derived from the stomach wall. – Minute calcareous rods is the usual skeleton in the internal tissues of the porcellanasterids). Numerous papulae is found in the main disk area. There is a distinct apical appendage. The madreporite is roundish or oval, close to the marginals, and with the striae radiating from a point located near its center, or between the center and the adcentral edge. The adambulacralia are rather elongate with a concave furrow margin, and a protruding adoral part on which is borne 2 diverging pointed spines (occasionally only one, or as many as 3 furrow spines). The furrow is broad and the podia are fairly large. The oral ossicles are large and broad, and, besides the single mouth-spine at their proximal junction, provided with 2-5 about as long, but more slender spines on their lateral margin. The ventrolateral area is armed with a pavement of plates, some of which with a single spinelet, extending as far as to the third inferomarginals,

from where the series of inferomarginalia and adambulacralia are contiguous, but possibly with the ends of the ambulacralia showing between them. The type-specimen of *S. vaneyi,* with R/r 20/10 mm, has 5 superomarginals and 11 adambulacralia. The largest specimen of *Sidonaster* on record, R/r 36/15 mm, has 7 superomarginals and 15 adambulacralia.

Remarks:

Three nominal species of *Sidonaster* have been described: 1) the type-species *vaneyi* by KOEHLER in 1909, 2) *batheri,* also by KOEHLER in 1909, and 3) *psilonotus* by FISHER in 1913. As is discussed in the following, these however, may all be considered specifically identical.

Sidonaster vaneyi Koehler, 1909

Sidonaster vaneyi n. sp., KOEHLER 1909*a* pp. 37-39, pls. 3_6, 6_5, 10_3.

Sidonaster psilonotus, DÖDERLEIN 1921 pp. 16-17, pl. 3_{2-2d}.
Sidonaster psilonotus, LIEBERKIND 1932 pp. 291-293, text-figs. 12-13, pls. 4_{10-11}, 7_{1-2}.
Porcellanaster, resembling *cæruleus,* WOOD-MASON & ALCOCK 1891*a* p. 13.
Porcellanaster cæruleus, WOOD-MASON & ALCOCK 1891*b* p. 433 (Non *P. cæruleus* Wyville-Thomsen).

KOEHLER described his species *vaneyi* on the basis of a single specimen dredged by the Investigator in the Arabian Sea (st. 290: 24°53′N, 57°43′E, 1524-1340 m, green sand, 6.4° C.). It has R/r 20/10 mm; 5 superomarginals; 11 adambulacralia; terminal ossicle with 7 spines; dorsal disk area with a fairly dense armature of spinelets; oralia with 2 lateral spines besides the mouth-spine.

S. batheri, the other species which KOEHLER described in 1909, was based on 11 specimens collected by the Investigator in seven dredgings in the Arabian Sea and in the Bay of Bengal (st. 192: 15°11′N, 72°29′E, 1668-1703 m, grey ooze, 4.2°-4.6° C.; st. 194: 13°47′N, 72°04′E, 1630 m, grey ooze, 5° C.; st. 254: 11°17′N, 92°58′E, 1224 m, green mud, 6.1° C.; st. 299: 23°43′N, 58°52′E, 2376 m, green mud, 2.2° C.; st. 300: 24°16′N, 60°26′E, 2515-2130 m, green mud, 1.8° C.; st. 318: 7°28′N, 79°20′E, 1984 m, green mud, 2.7° C.; and a dredging without st. no.: 14°22′N, 74°21′E, 2070 m). The specimens range in size from R/r 13/6 to 26/10 mm, and the number of superomarginals varies from 5 to 7, independently of the size of the specimens. The species *batheri* should differ from *vaneyi* in having the dorsal spinelets restricted to narrow interradial bands besides to the central area, and in having as many as 4-5 lateral oral spines. These differences, as it will appear from the descriptions of the variation found in various populations of other porcellanasterids, are of no taxonomical importance whatsoever, and *batheri* may therefore be considered a synonym of *vaneyi.*

FISHER (1919) recorded under the name of *S. batheri* four specimens of *Sidonaster* from two Albatross dredgings in the Philippine region (st. 5215: 12°32′N, 123°35′E, 1147 m, green mud, 10.3° C.; and st. 5491: 9°24′N, 125°12′E, 1346 m, green mud, 11.3° C.). The largest specimen has R/r 36/15 mm, 5-7 superomarginals; 15 adambulacralia. Spinelets dorsally extending over an area intermediate between the spinelet-bearing areas in *vaneyi* and in KOEHLER's *batheri*; 2-4 lateral oral spines. The features of these specimens thus stresses the vagueness of the characters which KOEHLER thought distinguishing *batheri* from *vaneyi.* FISHER also notes concerning his specimens that: "It has in fact been difficult to decide what to name them."

S. psilonotus, the third and last species of *Sidonaster* described, was erected by FISHER (1913, 1919) for a single specimen dredged by the Albatross in an undefined locality in the Philippine region. It has R/r 22/11 mm; 7 superomarginal plates. Dorsal side almost completely naked, only provided with a small number of spinelets interradially near the cribriform organs (which feature should distinguish *psilonotus* specifically from *vaneyi* and *batheri).* Terminal ossicles with only 5 spines (instead of 7 as in the other forms). Oralia with 4 lateral spines. The difference believed to distinguish *psilonotus* as a separate species, is taxonomically worthless, and *psilonotus* is thus to be regarded as a further synonym of *vaneyi.*

DÖDERLEIN (1921) under the name of *psilonotus* recorded 10 specimens of *Sidonaster,* collected by the Siboga in three dredgings in the region of the Malay Archipelago (st. 88: 0°35′N, 119°08′E, 1301 m, grey mud; st. 175: 2°38′S, 130°33′E, 1914 m, grey and green mud; and st. 211: 5°41′S, 120°46′E,

1158 m, grey mud). Two specimens had R/r 7/3 and 19/8.5 mm, and 9 superomarginals respectively, and the larger one 11 adambulacralia. All specimens had 5 terminal spines. (DÖDERLEIN notes p. 17 that the inner longitudinal row of ventrolateral plates only is well developed as far as to the third marginal plate, and from there to the end of the arm appears as a row of small triangular plates. – The latter statement, however, rests on a misinterpretation of the visible ends of the adambulacralia).

LIEBERKIND (1932) under the name of *psilonotus* recorded a single specimen of *Sidonaster,* dredged by the Valdivia in the western Indian Ocean off Somaliland (st. 257: 1°48′N, 45°42′E, 1644 m, globigerina ooze, blue mud, 4.6°C.). It has R/r 14/7 mm; 6-7 superomarginals; 10 adambulacralia. (LIEBERKIND did not give information of size or number of ossicles, but the present author has had occasion to re-examine the specimen). There are 5 terminal spines, and 4-5 lateral oral spines. LIEBERKIND notes that the differences between *psilonotus* and *batheri* are so unimportant that the two forms might well be only individual variations of the same species.

WOOD-MASON & ALCOCK (1891 p. 13) mention from off Goa (Investigator st. 105: 15°02′N, 72°34′E, 1353 m, globigerina ooze, 6.7°C.) a small porcellanasterid resembling *cæruleus,* which specimen KOEHLER (1909*a* p. 34) after a re-examination, stated to be a *Sidonaster.* It may be added that also the specimen which WOOD-MASON & ALCOCK (1891*b* p. 433) record from the Andaman Sea (Investigator st. 113: 12°59′N, 93°23′E, 1249 m, blue mud, 6°C.) under the name of *Porcellanaster cæruleus,* no doubt has been a *Sidonaster* too, considering the fairly high temperature at which it was found.

Distribution:

Sidonaster vaneyi, the only species in its genus, is hitherto collected in 17 dredgings (fig. 42) distributed in the northern Indian Ocean, from off the East African coast to the Malay Archipelago, the Philippines and New Guinea. It has been found at depths between 1147 and 2515-2130 m, on a bottom of grey ooze, globigerina ooze, and green and blue mud, and at temperatures ranging from 1.8° to 11.3°C.

ZOOGEOGRAPHICAL SURVEY

The Porcellanasteridae is, with a known bathymetrical range of from about one thousand to about seven thousand meters, one of the few exclusively deep-sea groups of higher taxonomic categories.

Three genera (all monotypic), *Lysaster, Benthogenia,* and *Sidonaster,* are confined – as far as is known – to the bathyal zone (depths of less than about 2000 m), and further seem to be restricted in their geographical distribution to the region of the Indian Ocean and the Malay Archipelago. (The two first mentioned are, however, recorded from only one and two finds respectively).

All other porcellanasterid genera occur in abyssal depths (i. e. are recorded from at least 2500 m), and, except *Abyssaster,* are known from all three oceans. *Hyphalaster, Thoracaster, Styracaster,* and *Abyssaster,* are exclusively abyssal. *Porcellanaster* and *Eremicaster* are also represented in bathyal depths (*P. cæruleus,* 1158-6035 m, and *E. pacificus,* 1571-4088 m). And *Eremicaster* reaches just into hadal depths (*E. vicinus,* 5204-about 7200 m).

Also a number of the species are recorded from all three oceans, and probably may be considered cosmopolitan (though perhaps in the Pacific known only from the western part, these marked with an asterisk), viz. *Hyphalaster inermis** (32 finds), *Thoracaster cylindratus* (20 finds), *Styracaster horridus** (15 finds), *Styracaster chuni** (6 finds, but yet none in the Indian Ocean), *Porcellanaster cæruleus* (86 finds), and *Eremicaster vicinus* (7 finds).

A single form, *Eremicaster pacificus* (15 finds), seems to be restricted to the eastern Pacific and the Bering Sea. Another, *Eremicaster gracilis* (23 finds), is known from the East Pacific and the western North Pacific, and has a very close relative, *E. crassus,* in the mid-Pacific and the Indian Ocean.

One species, *Styracaster elongatus* (7 finds), is recorded from both the Atlantic and the Indian Ocean. And also the species *Styracaster spinosus* occurs besides in the Atlantic (5 finds) probably also in the Indian Ocean, since the *S. clavipes* described from this region (1 find) may be the same species.

Two species, *Abyssaster tara* (8 finds) and *Styracaster armatus* (4 finds), are known from both the Indian Ocean and the western Pacific, and a third, *Eremicaster crassus* (5 finds), is known from the Indian Ocean and the mid-Pacific, and has further a very close relative, *E. gracilis,* in the East Pacific and western North Pacific.

Three species, *Hyphalaster scotiae, Styracaster ro-*

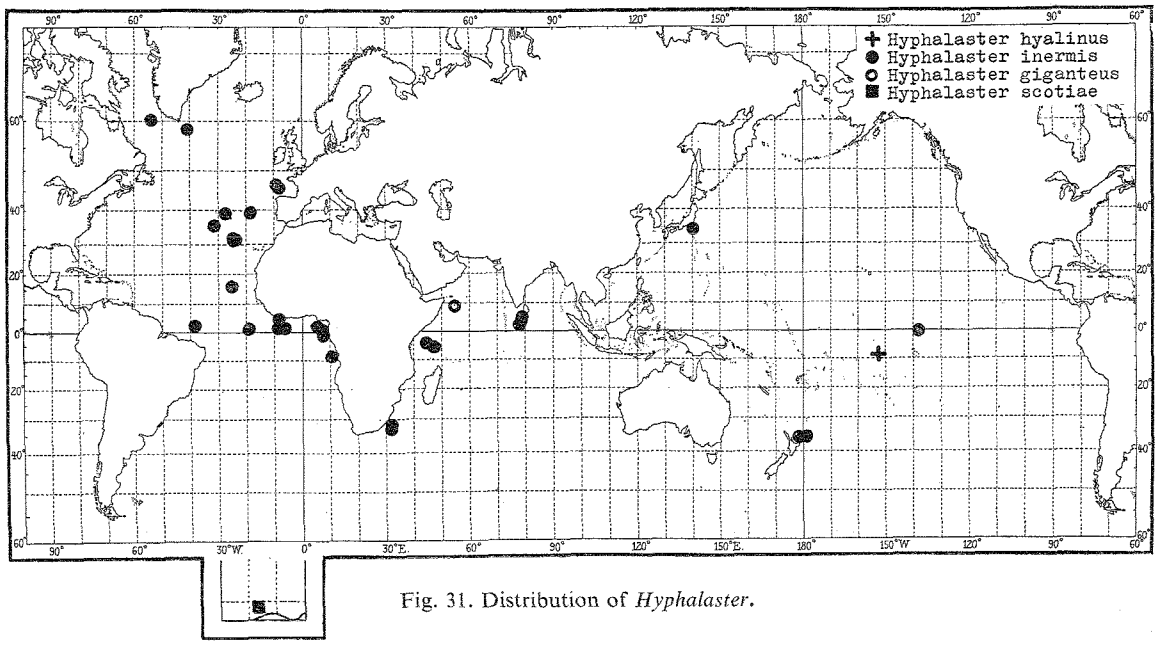

Fig. 31. Distribution of *Hyphalaster*.

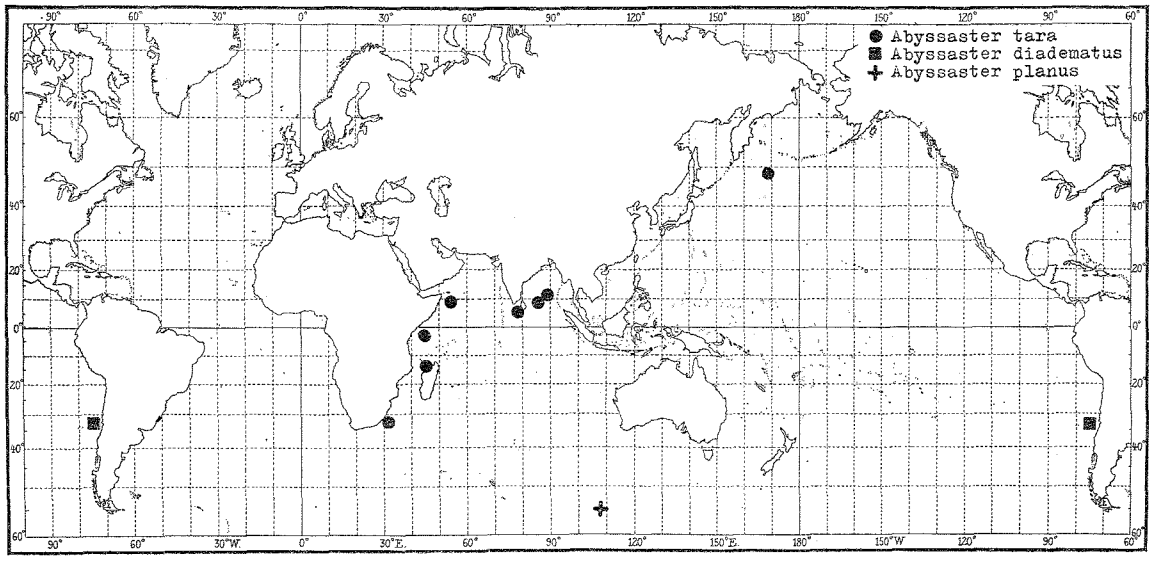

Fig. 32. Distribution of *Abyssaster*.

bustus, and *Abyssaster planus,* may be confined to the Antarctic region, but are hitherto only known from single finds.

The two porcellanasterid genera, *Porcellanaster* and *Eremicaster,* show an interesting distribution when considered together. They are the only ones known from bathyal as well as from abyssal finds, and both, as noted, may be said to have a cosmopolitan distribution. *Porcellanaster* (probably monotypic) is primarily Atlantic and Indo-West-Pacific in its distribution however (only three out of 86 records being from the eastern Pacific), while *Eremicaster* has primarily an Indo-pan-Pacific distribution (only the abysso-hadal *E. vicinus* being recorded once from the Atlantic). This pattern of distribution may perhaps indicate that *Porcellanaster* and *Eremicaster* are conquering the abyssal deep-sea from the bathyal North Atlantic and from the bathyal eastern Pacific respectively.

The main center of distribution of the Porcellanasteridae apparently is otherwise the Indo-Malayan region.

The porcellanasterids are found on a soft level bottom: greyish, greenish or bluish mud in about half of the 110 cases from which information is available; ooze in about one-third of the cases (usu-

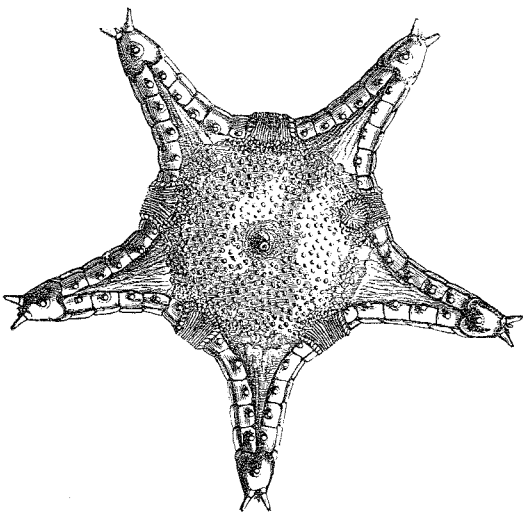
ally globigerina ooze, but in a few cases radiolarian ooze, and in one case diatom ooze); bluish, yellowish, brownish, reddish, greenish, or blackish clay in one-fifth of the cases; and, finally, green or black sand in a few cases.

The temperatures recorded for finds of porcellanasterids range from 0°C. to 11.5°C. The abyssal genera are found exclusively at temperatures below about 4°C.* Only the bathyal *Sidonaster* is thus known from the Sulu Sea in which the bottom temperature is about 10°C., and no porcellanasterids are known from the Mediterranean in which the bottom temperatures are above 12°C. Nor are any porcellanasterids known from the Arctic Sea or the Norwegian Sea with temperatures below 0°. The distribution of the porcellanasterids may to a great extent be controlled by the temperature, but it is noteworthy that no porcellanasterid has hitherto been found in shallower depths in the polar seas to where some other deep-sea groups of echinoderms have expanded their range.

Some species have a wide bathymetrical range, as *Porcellanaster cæruleus* (1158-6035 m) and *Eremicaster pacificus* (1571-4088 m), but other species known from a number of widely scattered finds were always obtained within definite zones of depths, e. g. *Styracaster horridus* (15 finds in all oceans, and all between 4040 and 5610 m) and *Eremicaster vicinus* (7 finds in all oceans, and all between 5204 and 7200 m).

* The bottom temperatures of the Challenger stations recorded by SLADEN in 1882 in centigrades were not correctly computed. The correct temperatures are given in degrees of Fahrenheit in 1889).



Porcellanaster cæruleus
The type-specimen, from WYVILLE THOMSON, 1877 fig. 98.
Nat. size.
